Rapid Assessment of the Presence of *Batrachochytrium dendrobatidis* in Bolivian Andean Frogs

The widespread chytrid fungus, *Batrachochytrium dendrobatidis* (*Bd*), causes a severe cutaneous infection to many species of amphibians worldwide, in some cases resulting in population declines or extinctions (Berger et al. 1998; Crawford et al. 2010; Lips et al. 2006; Mendelson et al. 2006). This fungus has been found in amphibians from five continents (Ron 2005; Une et al. 2008; www.Bd-maps.net), but has shown a broader geographic and taxonomic incidence in the Americas. Within South America, *Bd* has been reported from all countries except Paraguay and the Guianan region. In tropical America, the decline of many species in endemic genera and families, such as the genus *Atelopus* in the Bufonidae (La Marca et al. 2005), suggest a phylogenetically linked sensitivity to *Bd*. This may explain why the effects of chytridiomycosis in the Neotropics appear to be remarkably higher in relation to other continents (Corey and Waite 2008).

Given that *Bd* grows better in cool temperatures (17–23°C) (Piotrowski et al. 2004; Retallick et al. 2004), montane amphibian species are likely to be affected in tropical and sub-tropical areas. In the Andes, *Bd* has been found along the entire cordillera, with well-reported cases in Venezuela (Lampo et al. 2008) and Ecuador (Ron and Merino-Viteri 2000), and reports from more limited studies carried out in the Peruvian Andes (Catenazzi et al. 2011; Seimon et al. 2005, 2007; von May et al. 2008), Colombia (Ruiz and Rueda-Almonacid 2008; Velásquez et al. 2008), Argentina (Barrionuevo and Mangione 2006; Ghirardi et al. 2009) and Chile (Solís et al. 2009). The situation in Bolivia is less known; albeit the disease was assumed to be present because of the sudden declines observed in several species (Aguayo 2009; Cortez 2009; De la Riva 2005), it was not until recently that the first case of infection by *Bd* was documented (Barrionuevo et al. 2008). However, besides this particular case, the range of the disease and its taxonomic reach in Bolivia have been unknown. Our aim is to provide new qualitative information on the presence of *Bd* in Bolivia, and discuss patterns of amphibian declines in the area.

During February and March 2009, a rapid survey in the northern and central parts of the Bolivian Andes was done to get a better idea of the taxonomic and geographic occurrences of *Bd* (Fig. 1). Neither the total sample nor samples per species allowed for statistical analyses.

Geographic coverage for our study extended from the Chilean-Bolivian border in the Altiplano to the Cordillera Oriental in the Department of Chuquisaca, with a distance of nearly 500 km between the two most distant localities (1 and 4; see Fig. 1, Table 1) and an altitudinal range of 2650–4060 m. Four main types of habitats were surveyed (Table 2). Specimens, either adult or tadpoles, were collected by hand. Swabs were obtained by stroking the ventral pelvic patch and thighs of adults or the mouthparts of tadpoles using rayon swabs (Medical Wire 142). Selected voucher specimens were fixed in 70% ethanol and deposited in the herpetological collection of the Museo Nacional de Ciencias Naturales (MNCN, Madrid, Spain). Data on localities were recorded using a Global Positioning System (Table 1). Swabs were stored in their individual airtight plastic swab containers at ambient temperature in the high Andes (~ 15°C) during field work (30 days) and then at -20°C in the laboratory until processed for *Bd*. DNA extraction from swab samples was done using 50 µl of PrepMan Ultra (Hyatt et al. 2007). Detection and quantification of the level of infection by *Bd* on frog epidermal tissue was done with the Taqman qPCR method in an Applied Biosystems 7500 Real-Time PCR system according to Boyle et al. (2004). Infection intensity was calculated as the number of *Bd* zoospore genomic equivalents in each swab sample.

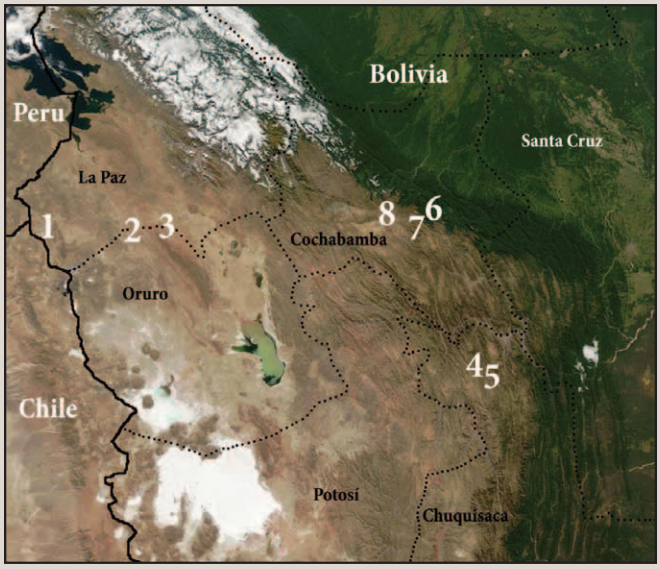

FIG. 1. Satellite map of the central Bolivian Andes showing the localities sampled for *Batrachochytrium dendrobatidis*, as numbered in Table 1. The dark blotch in the northwest is Lake Titicaca, on the Bolivian–Peruvian border; the white blotches in the south are the huge salt flats of Coipasa and Uyuni; near the center of the image is Lake Poopó.

We sampled 33 frogs of eight species and five families from eight different localities (Table 1). All individuals examined were apparently healthy, and no sick, dying, or dead individuals were found. Only one species, *Pleurodema cinereum*, was sampled in more than one locality (four locations). Overall, 18 of 33 (54.5%) individuals were infected with *Bd*, 6 of 8 species studied were *Bd*-positive, the infection was detected in all 4 habitat types sampled, and *Bd* was found at 7 of 8 localities surveyed (Tables 1 and 2). The level of infection among positive individuals was low, with *Bd* zoospore genomic equivalents ranging from 1–216 (mean = 16; SE = 11.1).

We found a broad distribution of *Bd* in the Bolivian Andes, covering all kinds of habitats from cloud forests to high puna. An overall prevalence greater than 50% and the low zoospore load in all populations convey that *Bd* is widespread and might be enzootic in this area, and that the amphibians sampled persist with low-level infections. Amphibians sampled in moister habitats, such as cloud forest and humid paramo, appeared to have higher prevalence of *Bd* than those from drier environments (puna and dry valleys), independent of altitude, (Table 2), although sample sizes were low preventing statistical comparisons. This suggests that in the high elevation Andes of Bolivia, humidity may favor maintenance of high zoospore reservoirs in the environment.

Different indirect data from the genus *Telmatobius,* which, like *Atelopus,* is endemic to the Americas and has declined drastically in the past 30 years, indicate that these frogs may be particularly vulnerable to chytridiomycosis (De la Riva and Lavilla 2008). The sudden decline of *T. espadai* and other species (De la Riva 2005) in the early 1990s in central Bolivia (Department of Cochabamba) lead us to believe that *Bd* might already have been there at that time. The presence of abundant *T. sanborni* near the Peruvian border in 2001 implies that *Bd* did not enter Bolivia following a north-south epidemic wave (sensu Lips et al. 2008), but rather the pathogen appeared independently in the central part of the country at a time when healthy *Telmatobius* populations were still thriving a few hundred kilometers to the northwest. Catastrophic *Telmatobius* declines started first in Ecuador (1980s), then in Bolivia (1990s) and later in Peru (2000s). Likewise, several *Telmatobius* species from northern Argentina had crashed by 2001 and surely their decline comes back to the early 1990s (Barrionuevo and Ponssa 2008). If the endemic pathogen hypothesis (Pounds et al. 2006) is not invoked, and we infer that these declines are a response to a *Bd* epidemic, then mechanisms to explain the uneven dispersal of *Bd* must be explored. Incubation and transport of viable *Bd* zoospores in bird feathers has been demonstrated *in vitro* (Johnson and Speare 2005). Thus, migratory birds might represent a means of dispersal and implicates potential multiple introductions across mountains and valleys in the high elevation Andes; this potential transmission vector should be further investigated in the wild.

In this paper we report the presence of *Bd* in several species across a large geographical area without apparent symptoms of disease. These results, as well as the evident disappearance or decline of many species in the area, particularly in the genus *Telmatobius*, suggest that the amphibian fauna of Bolivia may have already suffered a wave of chytridiomycosis whereby some species went extinct locally, others suffered bottlenecks from which they are probably recovering, and still others were infected but managed to endure. From a conservation standpoint, this potential scenario is worrisome because amphibians that persist with *Bd* may show decreased survival, and could be at risk from synergistic effects of this pathogen with other environmental stressors (Longo et al. 2009; Longo and Burrowes 2010). Furthermore, infected species can serve as both *Bd* reservoirs and vectors of *Bd* to nearby areas where amphibians may still be naïve to the fungus, and hence may contribute to subsequent losses. More fieldwork and *Bd* testing are needed to have a better understanding of the effects of *Bd* infection on Bolivian amphibians. Our study serves as a baseline for further *Bd*-related studies while identifying species and locations that might be currently at risk and should be prioritized when considering conservation and management programs in the Andes.

Acknowledgments.—Fieldwork and collecting permits in Bolivia were possible thanks to the collaboration of the personnel at the Colección Boliviana de Fauna, especially to J. Aparicio. Ignacio De la Riva is indebted to his field companions, J. M. Padial, N. Goicoechea, and T. Camacho. P. A. Burrowes is thankful to A. Alicea for assistance in molecular diagnosis of *Bd*. This paper was funded by project CLG2008-04164/BOS of the Spanish Ministry of Science and Innovation (I. De la Riva, Principal Investigator) and by Proyecto Coquí.

2012 Amphibian Ark calendars are now available!

The twelve spectacular winning photos from Amphibian Ark's international amphibian photography competition have been included in Amphibian Ark's beautiful 2012 wall calendar. The calendars are now available for sale, and proceeds from sales will go towards saving threatened amphibian species.

Pricing for calendars varies depending on the number of calendars ordered – the more you order, the more you save! Orders of 1-10 calendars are priced at **US$15 each**; orders of between 11-25 calendars drop the price to US$12 each; and orders of 26-99 are priced at just US$10 each. (These prices do not include shipping).

As well as ordering calendars for yourself, friends and family, why not purchase some calendars for re-sale through your retail outlets, or for gifts for staff, sponsors, or for fund-raising events?

Order your calendars from our web site:
www.amphibianark.org/calendar-order-form/

Additional Reports of the Amphibian Chytrid Fungus *Batrachochytrium dendrobatidis* from Georgia, USA

Batrachochytrium dendrobatidis (*Bd*), which causes the fungal disease chytridiomycosis, has been regarded as a contributing factor to worldwide amphibian declines (Daszak et al. 1999; Skerratt et al. 2007). *Bd* appears to be widespread within the southeastern United States, though relatively few surveys have been conducted to determine its prevalence within the region (Green and Dodd 2007; Hossack et al. 2010; Rothermel et al. 2008; Timpe et al. 2008). Our study further documents the occurrence and distribution of *Bd* in Georgia's amphibian populations with a focus on caudates. Georgia is home to a large and diverse assemblage of amphibian taxa, in particular salamanders (Jensen et al. 2008). We conducted surveys in four of five physiographic provinces in Georgia to document areas of occurrence. Subsequently, these areas can be more closely monitored over time, for example to determine *Bd*'s prevalence and any potential negative impacts as have been observed in other amphibian assemblages globally (Lips et al. 2006). This inventory-then-monitoring approach is especially important in regions of high amphibian diversity and endemism, such as Georgia.

We conducted surveys primarily in the Blue Ridge, Cumberland Plateau, and Piedmont physiographic provinces of Georgia from 5 March–12 September 2009. A small number of Striped Newts (*Notophthalmus perstriatus*) were opportunistically sampled during an unrelated survey in the Coastal Plain province (Table 1). Surveys took place on federal, state, county, and private land. Proper permissions from all stakeholders were acquired. While the main study focus was stream-dwelling and terrestrial caudates, anurans were also sampled when encountered. Only metamorphosed amphibians were sampled in this study. Three methods of detection were used: visual encounter, turning of cover objects (e.g., logs and rocks), and dip netting. A GPS coordinate was collected for each survey location (Garmin™ Oregon™ 400t; WGS 84). Once collected, each specimen was placed into an individual plastic container for a maximum period of 24 hours for on-site processing and was ultimately released at the point of capture. Powder-free vinyl or latex gloves were worn during all field collections with new gloves worn at each survey site. To prevent the spread of *Bd* or any other potential pathogens, a 10% bleach solution was used to disinfect all equipment (nets, boots, etc.) between survey sites.

Once each survey was completed, we swabbed specimens using polyester tipped plastic applicators (Fisherbrand®; Medical Wire & Equipment Company, Ltd.) following the method of Brem et al. (2007). A new set of gloves was used while swabbing each individual specimen. Each swab was placed into an individually numbered 1.8 ml plastic cryogenic vial for storage. Samples were refrigerated until shipment to the diagnostic lab at the College of Veterinary Medicine at North Carolina State University, Raleigh. Each sample was processed using *Bd*-specific real-time Taqman (Applied Biosystems, Foster City, CA) Polymerase Chain Reaction (PCR) according to the method of Boyle et al. (2004). Appropriate negative and positive controls were run concurrently with survey samples and the limit of detection was less than/equal to 0.5 zoospore equivalents.

From 5 March to 12 September 2009, we collected 300 samples from 21 caudate and nine anuran taxa in 11 Georgia counties (Table 1). Of these, *Bd* was detected in 11 samples from seven different taxa: Spotted Dusky Salamander (*Desmognathus conanti*), Seal Salamander (*D. monticola*), Southern Two-lined Salamander (*Eurycea cirrigera*), Red Salamander (*Pseudotriton ruber*), Eastern Newt (*Notophthalmus viridescens*), Green Frog (*Lithobates clamitans*), and Southern Leopard Frog (*L. sphenocephala*). With the exception of *E. cirrigera* (two positive results) and *N. viridescens* (four positive results), each of the remaining five taxa had one *Bd*-positive result (Table 2). None of the individuals that tested positive for *Bd* showed any obvious symptoms of chytridiomycosis (ventral redness, excessive skin sloughing, or diminished righting ability); they all appeared to be in overall good health at the time of collection.

Similar to past field studies examining *Bd* in southeastern United States amphibian populations (Green and Dodd 2007; Hossack et al. 2010; Rothermel et al. 2008; Timpe et al. 2008), overall detection of *Bd* in this study was low (< 4% of all samples). Eleven amphibians belonging to seven different taxa, including five caudate and two anuran species tested positive for *Bd* through PCR assay. The pathogen has been reported from all of these taxa in previous studies (Bakkegard and Pessier 2010; Byrne et al. 2008; Montanucci 2009; Rothermel et al. 2008; Timpe et al. 2008). It should be stated that sample size was small for many species (22 species with < 10 samples) such that our results may not accurately reflect the overall prevalence of *Bd* within the sampled populations (e.g., Skerratt et al. 2008).

Our detection of *Bd* on Eastern Newts (*N. viridescens*), Green Frogs (*L. clamitans*), and Southern Leopard Frogs (*L. sphenocephalus*) was not surprising because these species have produced numerous positive results within the southeastern United States, including Georgia (e.g., Bakkegard and Pessier 2010; Rothermel et al. 2008). Although our detections of *Bd* on a Seal Salamander (*D. monticola*), Southern Two-lined Salamanders (*E. cirrigera*), and a Red Salamander (*P. ruber*) are not the first for these three plethodontids (Byrne et al. 2009; Hossack et al. 2010; Montanucci 2009) our findings represent the first-reported occurrences in these species from the state of Georgia.

TABLE 2. Amphibians detected with *Batrachochytrium dendrobatidis* during our 2009 surveys in Georgia, USA.

Species	Age	Date	County	Location	Elevation (m)
Desmognathus monticola	Adult	2 April	Banks	34.40281°N, 083.58802°W	285.6
Desmognathus conanti	Adult	17 April	Walker	34.71059°N, 085.37840°W	296.9
Lithobates sphenocephalus	Juvenile	18 April	Walker	34.70395°N, 085.34389°W	274.9
Notophthalmus viridescens (4)	Adult	29 April	Rabun	34.97134°N, 083.43677°W	689.5
Eurycea cirrigera	Juvenile	29 August	Bartow	34.25626°N, 084.68904°W	256.9
Eurycea cirrigera	Juvenile	29 August	Bartow	34.25471°N, 084.68898°W	310.9
Pseudotriton ruber	Juvenile	10 September	Union	34.75878°N, 084.82399°W	709.6
Lithobates clamitans	Juvenile	10 September	Union	34.75878°N, 084.82399°W	709.6

The repeated detection of *Bd* on Spotted Dusky Salamanders (*D. conanti*) and Southern Leopard Frogs (*L. sphenocephalus*) at Crockford-Pigeon Mountain Wildlife Management Area in Walker County confirms the findings of Timpe et al. (2008). Long-term monitoring at this site warrants consideration because this is an exceptionally amphibian-rich area in Georgia (Jensen et al. 2008). This area is home to protected species such as the Green Salamander (*Aneides aeneus*), Tennessee Cave Salamander (*Gyrinophilus palleucus*), and endemic Pigeon Mountain Salamander (*Plethodon petraeus*). Only five individuals of *P. petraeus* were sampled during this study (Table 1), and although *Bd* was not detected on these individuals, a larger sample size would be required to properly determine prevalence in this species. Additional sampling effort is warranted for *P. petraeus* and other species with restricted ranges because studies have shown that terrestrial plethodontids may be detrimentally affected by chytridiomycosis in the wild (*Plethodon neomexicanus*, Cummer et al. 2005; three bolitoglossine species, Lips et al. 2006; *Batrachoseps attenuatus*, Weinstein 2009). Through experimental *Bd* inoculation, Vazquez et al. (2009) and Chinnadurai et al. (2009) found high susceptibility and mortality associated with chytridiomycosis in two species of terrestrial plethodontids (*Plethodon metcalfi* and *P. glutinosis*, respectively) but found two species of semi-aquatic plethodontids (*D. monticola* and *D. orestes*, respectively) showed few signs of illness and exhibited no mortality. The results of these experiments demonstrate that the overall effect of *Bd* on plethodontid salamanders is unclear and requires further focused study on populations in which it has been detected.

Acknowledgments.—The expert technical assistance of K. Gore, M. Perdue, and M. Suyemoto is gratefully acknowledged. Financial and logistical support were provided through Atlanta Botanical

Garden, North Carolina State University's College of Veterinary Medicine, Georgia Department of Natural Resources Wildlife Resources Division, United States Department of Agriculture Forest Service, the Hambidge Center for Creative Arts and Science, and the Gwinnett County Department of Parks and Recreation. Samples were collected under Georgia Department of Natural Resources Scientific Collecting Permit #29-WBH-09-133 and United States Department of Agriculture Forest Service – Chattahoochee-Oconee National Forest Research Collection Permit. The assistance of the following was invaluable to completion of this manuscript: A. Fusaro, A. Gray, A. Wallace, B. Davis, B. Everett, C. Eckard, C. Wentworth, D. Fenolio, D. Smith, E. Kabay, E. Travis, J. Cruse-Sanders , J. Jensen, J. Mendelson, III, J. Stabile, M. Mandica, M. Patterson, M. Richards, R. Determann, R. Gagliardo, S. Hanagud, the Georgia Herpetological Society, Emory University's Department of Environmental Studies, and Morehouse College's Upward Bound program.

Herpetology Courses and Graduate Programs: An Appeal

As an aid for students at all levels, SSAR is now compiling for its website a list of all herpetology courses and graduate programs, worldwide. This will be regularly updated. The list will cover all herpetology courses (or vertebrate biology courses having a sizable content on amphibians and reptiles) that are regularly taught at colleges, universities, biological stations, and other academic institutions anywhere in the world, with name of instructor and detailed course information. The availability of masters and/or doctoral degree-granting programs and names of relevant faculty and their contact information will be included.

Those who wish to have their courses and programs listed should send the following information (in this order, please):

1. Country (State or Province)
2. Institution: name and city
3. Department name
4. Course: number, title, frequency (annual or alternate years), undergraduate- and/or graduate-level course
5. Instructor: name and contact address (email if possible)
6. Graduate herpetology program: note if masters and/or doctoral level
7. Faculty involved in program: name and contact address (email if possible)
8. Special notes: limit to 30 words

Send this information to:

Prof. Kraig Adler
Cornell University
Mudd Hall, Ithaca, New York 14853–2702, USA
e-mail: kka4@cornell.edu

As soon as the list is compiled, a notice will appear in *Herpetological Review* that will indicate how the list may be accessed and updated. Please help to make this list as complete and useful as possible.

Herpetological Review, 2011, 42(3), 379–382.

Occurrence of *Batrachochytrium dendrobatidis* in Amphibian Populations of Okomu National Park, Nigeria

Amphibian declines are frequently due to a complex array of causative agents, many of which are poorly understood (Kiesecker et al. 2001; Garner et al. 2006). Although habitat destruction is the primary driver of biodiversity loss, infectious diseases have been identified as an important cause of some of the observed amphibian declines and mass mortalities (Skerratt et al. 2007). In particular chytridiomycosis caused by the amphibian chytrid fungus, *Batrachochytrium dendrobatidis* (*Bd*), has been associated with amphibian mass mortality events throughout the world (Berger et. al. 1998; Bosch et. al 2001; Lips 1998).

A number of surveys have established the occurrence of chytridiomycosis on the African continent, including South Africa (Hopkins and Channing 2003; Lane et al. 2003), Lesotho and Swaziland (Weldon 2005), Kenya (Kielgast et al. 2009), Tanzania (Moyer and Weldon 2006, Weldon and du Preez 2004), Uganda (Goldberg et al. 2007), Democratic Republic of Congo (Greenbaum et al. 2008), Ghana (Morgan et al. 2007), Gabon (Bell et al. 2011; Da Versa et al. 2011; Gratwicke et al. 2011) and Morocco (El Mouden et al. 2011). All of these records with the exception of those from Ghana are from wild caught animals. Some of the countries that represent the distribution gaps in sub-Saharan Africa (e.g., Guinea, Ivory Coast, Central African Republic) and Madagascar have been surveyed to some extent, but no evidence of *Bd* was found (Weldon 2005; Weldon et al. 2008). Furthermore, with the exception of Madagascar, small sample sizes restrict the reliability of the data from these surveys (e.g., Skerratt et al. 2008). Despite its prominence in Africa, chytridiomycosis has been associated with the extinction in the wild of only one species, the Kihansi Spray Toad from Tanzania (Weldon and du Preez 2004; Krajick 2006), although habitat alteration also was implicated in that species' decline (Krajick 2006). Contrary to the catastrophic host response in this east African case study, epidemiological evidence from histopathological studies indicates an endemic infection in southern Africa (Weldon et al. 2004).

Due to disparities in host response to chytridiomycosis in sub-Saharan Africa, a high degree of uncertainty exists with regards to how species from currently unsurveyed regions will respond to infection. Here we report on a *Bd* survey that was conducted in Okomu National Park, Nigeria between April 2007 and July 2008. Our objectives were to assess *Bd* occurrence in all amphibian species captured during a broad census of Okomu National Park. We also investigated whether any prevalence differences existed among amphibian families, sexes, and seasons. We hypothesized that males would have higher prevalence than females in aquatic-breeding species, because they are resident in water bodies for longer time periods in their search for mates. We expected higher prevalence to occur in the wet season rather than the dry season due to *Bd* being an aquatic-dependent fungus. We also expected similar prevalence among members of the same family due to their ecological similarities which predispose them to comparative *Bd* exposure.

Okomu National Park is situated within the largest block of what is now left of Guinea-Congo lowland rainforest in southwestern Nigeria and is characterized by a variety of habitats from swamp-forest to open scrub, making it ideal for amphibian diversity. It is situated between North latitudes 6°15′ and 6°25′, and East longitudes 5°9′ and 5°23′ (Fig. 1).

Frogs were captured monthly from April 2007 to July 2008 for a total of five dry season months and 10 rainy season months. Samples were collected by swabbing sterile cotton swabs five times over the ventral surface of the feet, thighs and body. Swab tips were stored in 2-ml screw-cap vials containing 1 ml of 70% ethanol. The samples were tested with TaqMan real time Polymerase Chain Reaction for the presence of amphibian chytrid fungus (Boyle et al. 2004). Unpaired t-test assuming equal variance was used to determine significant difference in overall prevalence of *Bd* between the two treatments wet and dry seasons and overall prevalence between the male and female treatment groups. Thus *Bd* is the response variable, and the combined species the experimental units. Chi-square test was used to test for significant difference in chytrid infection for each species (experimental units) between the wet and dry seasons and for each species between males and females.

A total of 732 frogs representing 10 families were sampled over the 15 month period. Of these, 7 families, 8 genera and 21 species were infected with *Bd* (Table 1). Members of the families Bufonidae, Dicroglossidae and Hemisotidae tested negative for *Bd*. An overall prevalence of 43.6% was recorded for infected species at Okomu National Park. The majority of frogs were collected during the wet season, which had an infection prevalence of 44%. Exceptionally high prevalence was detected for members of the Hyperoliidae (*Afrixalus nigeriensis*, up to 83%; *Silurana tropicalis*, 69%; and *Chiromantis rufescens*, 62%). Overall infection during the dry season was significantly lower at 33% ($p < 0.05$).

For the majority of species, more males than females were infected with *Bd* (Table 1). These differences between infected sexes were very particularly pronounced for *Afrixalus dorsalis* (100% males vs. 26.1% females infected, $p < 0.001$), *Hyperolius*

sylvaticus (86.6% males vs. 14.2% females infected, $p < 0.001$) and *Hyperolius* sp. 1 (40% males vs. 14.2% females infected, $p < 0.001$). Unpaired t-test confirmed that overall males were significantly more infected than females ($p < 0.001$). Generally, no clinical signs of chytridiomycosis could be observed except in *Chiromantis rufescens*, which exhibited excessive skin sloughing in 20% of animals. Microscopic examination of skin sloughs confirmed the presence of *Bd* thalli.

Although restricted to a small geographic area, our survey at Okomu National Park included a large enough sample size to make meaningful deductions. We confirm the presence of *Bd* in Nigeria, supporting an initial anecdotal report of infected *Chiromantis rufescens* (Imasuen et al. 2009). The level of infection that we detected in southwest Nigeria is among the highest that has been recorded anywhere in Africa. High infection levels in hyperolid frogs are consistent with previous findings in Tanzania (Moyer and Weldon 2006) and Kenya (Kielgast et al. 2009). However, large variation in *Bd* prevalence among members of the Hyperoliidae suggest that susceptibility to infection in this family is not only due to taxonomic relatedness, but that host-specific factors, such as behavior or reproductive mode, may be involved (e.g., Lips et al. 2003; Rowley and Alford 2007).

Two distinct patterns emerged from this study: heightened susceptibility to infection in the wet season and higher susceptibility to infection in males. In contrast to a peak in infection levels during the wet season, it has been shown that a cool climate (average summer maximum < 30°C) is the most significant factor for the presence of *Bd* in Australia, as opposed to rainfall or altitude (Drew et al. 2006). However, Collins et al. (2003) demonstrated that synchronization of optimal temperature and hydric cycles influence *Bd* growth. Clearly no single model exists to predict *Bd* seasonal infection patterns in populations from different geographical regions. Gender has been identified as a

FIG. 1. Location of *Batrachochytrium dendrobatidis* sampling at Okomu National Park, Nigeria.

TABLE 1. Seasonal and gender infection levels of *Batrachochytrium dendrobatidis* (*Bd*) at Okomu National Park, Nigeria.

Family and Species	No. frogs collected (% *Bd* infected)			
	Wet Season	Dry Season	Males	Females
ARTHROLEPTIDAE				
Leptopelis hyloides	17 (47.0)	13 (00.0)	21 (33.3)	9 (11.1)
Leptopelis spiritusnoctis	10 (20.0)	7 (00.0)	10 (10.0)	7 (14.3)
HYPEROLIIDAE				
Hyperolius concolor	4 (50.0)	—	3 (33.3)	1 (00.0)
Hyperolius fusciventris burtoni	9 (33.3)	6 (16.6)	9 (44.4)	6 (00.0)
Hyperolius picturatus	9 (22.2)	12 (33.3)	14 (42.8)	7 (00.0)
Hyperolius sylvaticus	18 (66.2)	4 (50.0)	15 (86.6)	7 (14.2)
Hyperolius sp. 1	10 (10.0)	7 (57.1)	10 (40.0)	7 (14.2)
Hyperolius sp. 2	5 (40.0)	4 (00.0)	6 (33.3)	3 (00.0)
Hyperolius sp. 3	3 (00.0)	2 (50.0)	4 (25.0)	1 (00.0)
Hyperolius sp. 4	5 (40.0)	—	3 (66.2)	2 (00.0)
Afrixalus dorsalis	82 (75.6)	26 (46.1)	62 (100)	46 (26.1)
Afrixalus nigeriensis	42 (83.3)	—	35 (94.3)	7 (28.5)
Afrixalus paradorsalis	6 (66.6)	—	5 (80.0)	1 (0.00)
PHRYNOBATRACHIDAE				
Phrynobatrachus calcaratus	22 (54.5)	3 (00.0)	18 (38.9)	7 (71.4)
Phrynobatrachus liberiensis	9 (44.4)	16 (50.0)	20 (40.0)	5 (0.00)
Phrynobatrachus plicatus	22 (27.2)	11 (00.0)	21 (19.0)	12 (16.6)
PIPIDAE				
Silurana tropicalis	100 (65.0)	42 (54.7)	78 (78.2)	64 (57.8)
PTYCHADENIDAE				
Ptychadena longirostris	27 (3.7)	—	23 (4.3)	4 (00.0)
Ptychadena pumilio	5 (00.0)	30 (20.0)	17 (11.7)	18 (16.6)
RANIDAE				
Amnirana albolabris	6 (33.3)	5 (20.0)	7 (42.6)	4 (50.0)
RHACOPHORIDAE				
Chiromantis rufescens	60 (61.7)	4 (75.0)	38 (68.4)	26 (53.8)

factor that influences disease expression in humans and animals due to differences in behavior and physiology (Mohamed-Ali et al. 1999; Liesenfeld et al. 2001). In frogs, such behavioral differences are pronounced in species that make use of a prolonged breeding strategy where reproductive activity may range from a few weeks to several months. Since female arrival at breeding sites occur at variable intervals, males invest their energy in the establishment and defense of stationary call sites, resulting in large aggregations of calling males (Wells 1977). Choruses are characterized by a high turnover of individual males, because vocalization is energetically expensive and males regularly need to replenish energy reserves (Passmore and Carruthers 1995). It is therefore plausible that general differences in gender infection levels could be as a result of males congregating for longer at *Bd*-infected sites. Our understanding of the disease dynamics of chytridiomycosis in Africa remains limited.

The lack of comprehensive distribution data for *Bd* on this continent, together with the unpredictability of how amphibian species from different climatic regions react to *Bd*, as well as quantitative data on how disease transmission is shared among sexes of a species, warrants the need for comprehensive field surveillance.

Acknowledgments.—We appreciate the financial support of the Department of Science and Technology, South Africa and the assistance of the officials and staff of Okomu National Park Nigeria. Mr. Festus Arijiode and Mr. Elisha Enabulele are also thanked for their technical assistance during the study.

ART IN HERPETOLOGY

The unpublished watercolor drawing of a Western Pond Turtle (*Actinemys marmorata*) figured here is one of more than 900 scientific illustrations in the Ernst Mayr Library's Jacques Burkhardt Collection, held at the Museum of Comparative Zoology (MCZ), Harvard University. This undated scientific illustration was drawn by artist Jacques Burkhardt, the personal and principal artist of MCZ founder Jean Louis Rodolphe Agassiz. Agassiz had commissioned such drawings in support of his seminal endeavor, *Contributions to the Natural History of the United States of America*, an anticipated 10-volume set of which only four volumes were realized. Lithographer A. (Auguste) Sonrel successfully adapted many of Burkhardt's turtle drawings for Agassiz's *Contributions* (vol. I: North American Testudinata, and vol. II: Embryology of the Turtle); however, this drawing of an adult specimen from San Francisco, California, was not selected for publication in Agassiz's failed masterpiece. The manuscript annotation penciled by Agassiz himself reads, "To be compared with *Emys nigra* Hallowell; from Lower California. This is from San Francisco." Agassiz's annotation no doubt refers to a second unpublished Burkhardt drawing of an adult Western Pond Turtle specimen collected in Southern California by naturalist Spencer Fullerton Baird. Additional information about the Jacques Burkhardt Collection can be found at: http://library.mcz.harvard.edu/. Special thanks to MCZ Director James Hanken for permitting reproduction of Burkhardt's work here.

GEOGRAPHIC DISTRIBUTION

CAUDATA — SALAMANDERS

***AMBYSTOMA MACULATUM* (Spotted Salamander)**. USA: GEORGIA: Rabun Co.: 6.1 km NNE Pine Mountain. Heddon Bog, Chattahoochee National Forest (34.98941°N, 83.152288°W; NAD 83). 12 March 2011. C. Jenkins and D. Stevenson. Verified by Lance D. McBrayer. GSU 18983. New county record (Jensen et al. [eds.] 2008. The Amphibians and Reptiles of Georgia. University of Georgia Press, Athens. 575 pp.).

CHRISTOPHER L. JENKINS and **DIRK J. STEVENSON**, The Orianne Society, Indigo Snake Initiative, 571 Hwy. 441 South, Clayton, Georgia 30525, USA.

***AMBYSTOMA TALPOIDEUM* (Mole Salamander)**. USA: ALABAMA: Montgomery Co.: City of Montgomery, Cypress Pond Park, 1.8 km NE of the Alabama State Capitol Building (32.39117°N, 86.29076°W; WGS84; elev. 61 m). 29 November 2010. Eric C. Soehren and William A. Campbell. Photographic voucher (AUM AHAP-D 298). Verified by Craig Guyer. New county record (Mount 1975. Reptiles and Amphibians of Alabama. Agricultural Experiment Station, Auburn University, Alabama. 347 pp.). Hand captured five individuals in forested wetland dominated by mature *Nyssa aquatica* (Water Tupelo) with scattered *Taxodium distichum* (Bald-cypress). *A. talpoideum* was found in association with *A. opacum* underneath decaying logs over saturated soil near pools of standing water. A comprehensive query of museum holdings through HerpNET (www.herpnet.org) revealed four previously unpublished vouchered specimens collected in Montgomery Co. They include one specimen collected in 1954 by R. L. Chermock (UAHC 7303) and three specimens collected on 3 May 1977 by S. N. Levy and R. O. Magram (CMNH 64991–64993). Collectively, these records partially fill in a gap between Dallas and Macon counties in the upper Coastal Plain of Alabama (Mount 1975, *op. cit.*).

We thank C. Guyer for verifying this record; L. Rissler and R. Downer for providing specimen information from UAHC; and S. Graham for reviewing this note.

ERIC C. SOEHREN, Alabama Department of Conservation and Natural Resources, State Lands Division, 64 N. Union Street, Suite 464, Montgomery, Alabama 36130, USA (e-mail: eric.soehren@dcnr.alabama.gov); **WILLIAM A. CAMPBELL**, 2220 Rosemont Drive, Montgomery, Alabama 36111, USA (e-mail: bcampbell06@knology.net).

***AMBYSTOMA TEXANUM* (Small-mouthed Salamander)**. USA: ARKANSAS: Calhoun Co.: 2 km N of Calion, Ouachita River backwaters off US 167; (33.346344°N, 92.532132°W; no datum). 01 April 2011. M. B. Connior. Verified by S. E. Trauth. New county record (Trauth et al. 2004. The Amphibians and Reptiles of Arkansas. University of Arkansas Press, Fayetteville. 421 pp.). Arkansas State University Museum of Zoology Herpetology Collection (ASUMZ 31640). This adult individual was hand captured under a log in a small slough.

MATTHEW B. CONNIOR, Health and Natural Sciences, South Arkansas Community College, 300 S. West Avenue, El Dorado, Arkansas 71730, USA; e-mail: mconnior@southark.edu.

***AMPHIUMA TRIDACTYLUM* (Three-toed Amphiuma)**. USA: MISSISSIPPI: George Co.: Upper Rines Lake, Pascagoula River Wildlife Management Area (30.818172°N, 88.734579°W; NAD83). 16 April 2011. James R. Lee and Donald J. Newman III. Verified by Robert L. Jones. Mississippi Museum of Natural Sciences (MMNS 17443). New county record (Boundy 2005. *In* M. Lannoo [ed.], Amphibian Declines: The Conservation Status of United States Species, pp. 646–647. Univ. of California Press, Berkeley, California). Including this record, the species has been reported from each county in Mississippi except Tishomingo and Jackson counties (Boundy, *op. cit.*). *A. tridactylum* occurs sympatrically with *A. means* at this site.

JAMES R. LEE (e-mail: jlee@tnc.org) and **DONALD J. NEWMAN III,** The Nature Conservancy, Camp Shelby Joint Forces Training Center, CS-JFTC-ENV Building 622, Camp Shelby, Mississippi 39407, USA.

***EURYCEA CHAMBERLAINI* (Chamberlain's Dwarf Salamander)**. USA: GEORGIA: Baldwin Co.: Baldwin State Forest; collected under sphagnum moss on the edge of a beaver pond (32.98201°N, 83.21257°W; WGS 84). 18 May 2011. S. Graham and J. Jensen. Verified by Craig Guyer. AUM 39511. New county record (Jensen et al. [eds.] 2008. The Amphibians and Reptiles of Georgia. University of Georgia Press, Athens, 575 pp.). This record fills a ca. 70 km distribution gap for this species between the nearest record to the west in Crawford Co., Georgia (Jensen et al. [eds.] 2008, *op. cit.*), and populations ca. 120 km E in Barnwell Co., South Carolina (Harrison and Guttman 2003. Southeast. Nat. 2:159–178). Specimens of *Eurycea quadridigitata* reported from this county previously (Jensen et al. [eds.] 2008, *op. cit.*) were collected before the description of *E. chamberlaini*, and are probably attributable to that taxon.

We thank Brian Lowe and Dennis Parmley for information about this site.

BRIGGS** and **DIRK J. STEVENSON**, The Orianne Society, Indigo Snake Initiative, 571 Hwy. 441 South, Clayton, Georgia 30525, USA.

***PSEUDOTRITON RUBER RUBER* (Northern Red Salamander)**. USA: TENNESSEE: Union Co.: Maynardville (36.169942°N, 83.890781°W, WGS84). 10 October 2010. Stephen K. Nelson. Verified by A. Floyd Scott. David H. Snyder Museum of Zoology, Austin Peay State University (APSU 19117, color photo). First county record (Redmond and Scott 1996. Atlas of Amphibians in Tennessee. Misc. Publ. No. 12, The Center for Field Biology, Austin Peay State University, 24 pp. Internet version available at http://www1.apsu.edu/amatlas/index.html, accessed 13 April 2011). On road at night in light rain. Temperature 15.5°C.

STEPHEN K. NELSON, University of Tennessee, Knoxville, Tennessee 37996-0925, USA; snelso24@utk.edu.

ANURA — FROGS

***ANAXYRUS COGNATUS* (Great Plains Toad)**. USA: TEXAS: Motley Co.: North of Matador, Texas on Farm to Market Road 2009 (34.163056ºN, 100.938611ºW; WGS 84; elev.796 m). 14 August 2008. Andrew M. Brinker and Gary W. Ferguson. Verified by Carl J. Franklin. University of Texas at Arlington Digital Slide Collection (UTADC 4030). New county record, fills gap in range (Dixon 2000. Amphibians and Reptiles of Texas, 2nd ed. Texas A&M Univ. Press, College Station, Texas. 421 pp.).

ANDREW M. BRINKER, Department of Science, R. L. Paschal High School, Fort Worth, Texas 76110, USA; e-mail: andrew.brinker@fwisd.org.

***CHIROMANTIS DORIAE* (Doria's Asian Treefrog)**. CHINA: GUANGDONG: Leizhou (20.841011°N, 109.994461°E; WGS 84; 8 m elev.). 25 June 2011. H.-K. Chan, R.-L. Li, and W.-L. Tse. Verified by Y.-Y. Wang. Sun Yat-Sen University, The Museum of Biology (SYS a001192–1197). First record for Guangdong Province. Extends distribution ca. 150 km into mainland China from nearest offshore Hainan Island (Fei et al. 2009. Fauna Sinica: Amphibia. Vol. 2: Anura. Chinese Academy of Science, Beijing, pp. 730–734), and outside range maps of IUCN Red List (http://www.iucnredlist.org/apps/redlist/details/58787/0) and AmphibiaWeb (http://amphibiaweb.org/cgi-bin/amphib_map?genus=Chiromantis&species=doriae). Males found perching on rice plants, 1 m above ground and actively calling.

HON-KI CHAN, School of Biological Sciences, The University of Hong Kong, Hong Kong (e-mail: honkichan@gmail.com); **JIAN-HUAN YANG,** The Museum of Biology, Sun Yat-Sen University, Guangzhou, Guangdong, China (e-mail: philautus@yahoo.com).

***HYLA CINEREA* (Green Treefrog)**. USA: OKLAHOMA: Marshall Co.: Fobb Bottom ca. 3.4 air km WSW of Willis; 14S (33.88556°N, 96.86557°W; WGS84). 25 May 2011. Richard D. Butler and David A. Juarez. Verified by Charles W. Painter. Sam Noble Oklahoma Museum of Natural History (OMNH 43542–43543). New county record (Sievert and Sievert 2011. A Field Guide to Oklahoma's Amphibians and Reptiles, 3rd ed. Oklahoma Dept. Wildlife Cons. vi + 211 pp.). Known populations occur in Johnston Co. ca. 40 air km to the northeast. Calling males were abundant in a shallow wetland, air temperature 25.6°C.

RICHARD D. BUTLER, RR 4 Box 79, Okemah, Oklahoma 74859, USA; **DAVID A. JUAREZ**, 2624 NE 1095th Avenue, Red Oak, Oklahoma 74563, USA.

***HYPOPACHUS BARBERI* (Montane Sheep Frog)**. HONDURAS: LA PAZ: ca. 10 km W of Guajiquiro (14.08792°N, 87.50654°W; WGS84), 2160 m elev. 24 May 2008. César A. Cerrato M., Lorraine P. Ketzler, Ileana R. Luque-M., Josiah H. Townsend, and Larry David Wilson. Verified by Max A. Nickerson. UF 152967 (series

of 18 samples). Easternmost record for this species in Central America and a ca. 28 km range extension ENE of Cantón Sabaneta, La Paz, Honduras (KU 184853–54; McCranie and Wilson 2002. The Amphibians of Honduras. SSAR Cont. Herpetol. 19, Ithaca, New York. x + 625 pp.). The frogs were collected from a breeding aggregation in a small cattle pond at the edge of a pasture located near a remnant patch of cloud forest.

ILEANA R. LUQUE-MONTES, Departamento de Biologia, Universidad Nacional Autónoma de Honduras, Tegucigalpa, Honduras (e-mail: ileanaluquem@gmail.com); **LORRAINE P. KETZLER,** Voluntaria de Cuerpo de Paz, San Isidro, Santa Cruz de la Yojoa, Honduras; **CÉSAR A. CERRATO MENDOZA,** Departamento de Biologia, Universidad Nacional Autónoma de Honduras, Tegucigalpa, Honduras**; LARRY DAVID WILSON,** 16010 SW 207th Ave., Miami, Florida 33187, USA; **JOSIAH H. TOWNSEND,** School of Natural Resources and Environment, and Florida Museum of Natural History, University of Florida, Gainesville, Florida 32611-7800, USA.

HYPSIBOAS PULCHELLUS **(Montevideo Treefrog, Ranita del Zarzal)**. ARGENTINA: SAN LUIS PROVINCE: capital city of San Luis, north shore of the Chorrillos river (San Luis river), between 33.308°S, 66.321°W and 33.303°S and 66.317°W (datum WGS84). 9 December 2009, 4 November and 9 December 2010. M. Calderón and M. Jofré. University of San Luis Herpetological Collection, San Luis, Argentina (CH-UNSL 0438–0439, 0452–0454). Verified by B. Espeche. *Hypsiboas pulchellus* is a widespread and abundant species, with an extensive distribution in Buenos Aires, Córdoba, Corrientes, Chaco, Entre Ríos, Misiones, La Pampa, and Santa Fe provinces in Argentina (Lavilla et al. 2000. *In* Lavilla et al. [eds], Categorización de los Anfibios y Reptiles de la República, pp. 2–25. Asociación Herpetológica Argentina). It is also distributed in Uruguay; Rio Grande do Sul and Santa Catarina in Brazil; and southern Paraguay (Nuñez et al. 2004. Smithson. Herpetol. Inform. Serv. 134; Machado and Maltchik 2007. Neotrop. Biol. Conserv. 2[2]:101–116; Colombo et al. 2008. Biota Neotrop. 8[3]:229–240). First province record and the westernmost in Argentina, extending range ca. 187 km W from the nearest locality known, Río Cuarto in Córdoba province (Kwet et al. 2004. *In* IUCN 2010. IUCN Red List of Threatened Species. Version 2010.4. <www.iucnredlist.org>. Downloaded on 06 March 2011; Martori and Avila 1992. Bol. Asoc. Herpetol. Arg. 8[1]:4–5;).

ISCHNOCNEMA VERRUCOSA. BRAZIL: BAHIA: Municipality Amargosa: Timbó Farm (13.0721°S, 39.3940°W; SAD 69) 750 m elev. 10 January 2007. B. Hamdan. Museu de Zoologia da Universidade Federal da Bahia, Salvador, Bahia, Brazil (MZUFBA 6436, colected on the ground of Atlantica Rain Forest). Verified by M. Napoli. Previously known from the type locality in Minas Gerais, two localities in Espírito Santo, and one locality in the municipality of Camacan, state of Bahia (Dill Orrico 2010. Check List 6[2]:246–247; Frost 2011. Amphibian Species of the World. An Online Reference. Version 5.5 (17 April 2011); electronic database accessible at http://research.amnh.org/vz/herpetology/amphibia/, accessed 17 April 2011; American Museum of Natural History, New York). Record extends known distribution ca. 260 km N from Municipality of Camacan, Bahia, Brazil (Dill Orrico 2010, op. cit.).

MARCO ANTÔNIO DE FREITAS, Programa de pós-graduação em zoologia, UESC (Universidade Estadual de Santa Cruz) CEP 46.500-000 Rodovia Ilhéus/Itabuna, Ilhéus, Bahia (e-mail: philodryas@hotmail.com); **BRENO HAMDAN DE SOUZA** (e-mail: brenohamdan@gmail.com) and **PATRÍCIA MENDES FONSECA,** Universidade Federal da Bahia, Laboratório AMPHIBIA, Campus de Ondina, Salvador, Bahia, Brazil CEP 40.000-000 (e-mail: patriciamfonseca@yahoo.com.br).

LITHOBATES JOHNI **(Moore's Frog)**. MÉXICO: HIDALGO: Municipality of Huehuetla: Río Blanco (20.24646°N, 98.05434°W, WGS84: 601 m elev.). 15 March 2011. Christian Berriozabal-Islas, A. Ramírez-Bautista, and Luis Badillo-Saldaña. Colección Herpetológica del Centro de Investigaciones Biológicas, Universidad Autónoma del Estado de Hidalgo (CIB 4114-4120). Municipality of Tepehuacán de Guerrero: Río San Simón (20.00499°N, 98.49262° W, WGS84; 323 m elev.) 20 March 2011. Luis Badillo-Saldaña, Christian Berriozabal-Islas, Uriel Hernández-Salinas, and Jorge Tomás-Villegas. CIB 4127.. Municipality of Yahualica: Río Naranjos (20.54135°N, 98.25063°W, WGS84: 254 m elev.) 22 March 2011. Luis Badillo-Saldaña, Christian Berriozabal-Islas, Uriel Hernández-Salinas, and Jorge Tomás-Villegas. CIB 4128-4131. All are first municipality records and were verified by Adrian Leyte-Manrique. The records bridge a previous distributional gap between the only other known locality from Hidalgo on Río Pachula, Municipality of Calnali (Ramírez-Bautista et al. 2010. Lista Anotada de los Anfibios y Reptiles del Estado de Hidalgo, México. Univ. Autón. del Estado de Hidalgo, CONABIO, México D.F. x + 104 pp.) and near Arroyo Sacahuite, Palictla, Tamazunchale, San Luis Potosí (Blair 1947. Amer. Mus. Nov. [1353]:1–17). The frogs were found in rivers and fast flowing streams surrounded by tropical evergreen forest.

We thank A. Leyte-Manrique and U. Hernández-Salinas for logistical help. This study was funded by CONACYT-S 52552-Q and FOMIX-HGO-2008-95828.

***PHRYNOBATRACHUS PALLIDUS* (Pale Puddle Frog)** KENYA: COAST PROVINCE: north end of Lake Peccatoni (alternative names: Lake Mpeketoni, Lake Mukunguya), northeast of Witu (2.416667°S, 40.683333°E; NIMA GNS database). 24 May 1934. A. Loveridge. MCZ A-20425–9. Kakoneni (3.169967S°, 39.86283E°; WGS84). 6 May 2000. D. R. Buchholz, T. B. Hayes, A. Vonk, E. Marquez, and A. Espira. MVZ 234153. Verified by José Rosado. Verification supported by mitochondrial data from 12S and 16S ribosomal DNA, transfer RNA valine, and nuclear data from the RAG-1 gene (Zimkus et al. 2010. Mol. Phylogenet. Evol. 55:883–900). Species previously known with certainly from coastal Tanzania, between Dar es Salaam and Tanga, with an unsubstantiated location at Lake Mpeketoni, Kenya (locality of MCZ A-20425–9 erroneously identified as Lake Kenyatta; Pickersgill 2007. Frog Search: Results of Expeditions to Southern and Eastern Africa. Edition Chimaira, Frankfurt am Main. 575 pp.). Loveridge (1936. Bull. Mus. Comp. Zool. 79:369–430) remarked that Lake Mpeketoni population morphologically different from other Kenyan populations of *P. minutus* (equivalent to *P. schefferi*), with specimens exhibiting well-defined digital disks, white throats, and overall pale coloration. First confirmed records for Kenya, extending range >340 km NNE from holotype locality in Tanga, Tanzania, to Lake Mpeketoni, Kenya. Presence of *P. pallidus* at these localities suggests species may be found in additional coastal areas in southern Kenya.

BREDA M. ZIMKUS, Department of Organismic and Evolutionary Biology, Harvard University, 26 Oxford Street, Museum of Comparative Zoology, Cambridge, Massachusetts 02138, USA; e-mail: bzimkus@oeb.harvard.edu.

***PSEUDACRIS FERIARUM* (Upland Chorus Frog)**. USA: TENNESSEE: Union Co.: Maynardville (36.197958°N, 83.896322°W; WGS84). 10 October 2010. Stephen K. Nelson. Verified by A. Floyd Scott. David H. Snyder Museum of Zoology, Austin Peay State University (APSU 19116, color photo). First county record (Redmond and Scott 1996. Atlas of Amphibians in Tennessee. Misc. Publ. No. 12, Center for Field Biology, Austin Peay State University, 24 pp. Internet version, available at http://www1.apsu.edu/amatlas/index.html, accessed 12 April 2011). On road at night in light rain. Temperature 15.5°C.

STEPHEN K. NELSON, University of Tennessee, Knoxville, Tennessee 37996-0925, USA; snelso24@utk.edu.

***PSEUDACRIS MACULATA* (Boreal Chorus Frog)**. USA: NEBRASKA: Franklin Co.: 4.9 km S, 9.0 km W Hildreth (40.292467°N, 99.1579°W; NAD1983). 12 July 2009. Keith Geluso. Verified by Curtis J. Schmidt, Sternberg Museum of Natural History, Fort Hays State University, Hays, Kansas (MHP 14703). First county record. Fills distributional gap in south-central Nebraska (Ballinger et al. 2010. Amphibians and Reptiles of Nebraska. Rusty Lizard Press, Oro Valley, Arizona. 400 pp.; Fogell 2010. A Field Guide to the Amphibians and Reptiles of Nebraska. University of Nebraska, Lincoln. vi + 158 pp.). Known from adjacent Webster Co. to the east and Kearney Co. to the north (Fogell 2010, *op. cit.*). Captured in a flooded roadside area adjacent to an agricultural field.

KEITH GELUSO, Department of Biology, University of Nebraska at Kearney, Kearney, Nebraska 68849, USA; e-mail: gelusok1@unk.edu.

***SCAPHIOPUS COUCHII* (Couch's Spadefoot)**. USA: TEXAS: Motley Co.: North of Matador, on Farm to Market Road 2009 (34.175°N, 100.955556°W; WGS 84, elev. 812 m). 14 August 2008. Andrew M. Brinker and Gary W. Ferguson. Verified by Carl J. Franklin. University of Texas at Arlington Digital Slide Collection (UTADC 4029). New county record fills gap in range (Dixon 2000. Amphibians and Reptiles of Texas, 2nd ed. Texas A&M Univ. Press, College Station. 421 pp.).

ANDREW M. BRINKER, Department of Science, R. L. Paschal High School, Fort Worth, Texas 76110, USA; e-mail: andrew.brinker@fwisd.org.

***SCAPHIOPUS HOLBROOKI* (Eastern Spadefoot)**. USA: GEORGIA: Early Co.: Williams Bluff Preserve (31.199688°N, 85.083085°W; WGS 84; elev. 52 m). 10 April 2011. Robert L. Hill. Verified by John Jensen. UTADC 6907. New county record (Jensen et al. [eds.] 2008. Amphibians and Reptiles of Geórgia. Univ. of Georgia Press, Athens. 575 pp.); previously documented in adjacent Crawford, Macon, and Marion counties. Found inside of a rotting log on a hillside ~1.2 km W of Hwy 370. Specimen was photographed and released.

ROBERT L. HILL, Department of Research and Conservation, Atlanta Botanical Garden, Atlanta, Georgia 30309, USA; e-mail: rhill@atlantabotanicalgarden.org.

***SCAPHIOPUS HOLBROOKII* (Eastern Spadefoot)**. USA: INDIANA: Greene Co.: 3.44 km E of the West Fork of the White River. (38.91506°N, 87.04493°W; NAD 83). 19 April 2011. Sarabeth Klueh and Jason Mirtl. Verified by Chris Phillips. Illinois Natural History Survey (INHS 2011-I, photographic voucher). New county record for Indiana (Minton. 2001. Amphibians and Reptiles of Indiana.

2nd ed., revised. Indiana Academy of Science. vii + 404 pp.) Adult male observed at night in a flooded agricultural field. This record fills gap for Indiana. There were existing records for counties south, west, and north of Greene Co..

SARABETH KLUEH (e-mail:sklueh@dnr.in.gov.) and **JASON MIRTL,** Wildlife Diversity Section, Indiana Department of Natural Resources Division of Fish and Wildlife, 553 E. Miller Drive, Bloomington, Indiana 47401, USA.

***SPEA BOMBIFRONS* (Plains Spadefoot)**. USA: Franklin Co.: 4.0 km S Wilcox (40.32965°N, 99.16133°W; NAD1983). 12 July 2009. Keith Geluso. Verified by Curtis J. Schmidt, Sternberg Museum of Natural History, Fort Hays State University, Hays, Kansas (MHP 14709). First county record. Fills distributional gap in south-central Nebraska (Ballinger et al. 2010. Amphibians and Reptiles of Nebraska. Rusty Lizard Press, Oro Valley, Arizona. 400 pp.; Fogell 2010. A Field Guide to the Amphibians and Reptiles of Nebraska. University of Nebraska, Lincoln. vi + 158 pp.). Captured on road surrounded by agricultural fields. Phelps Co.: Funk-Odessa Road, 17.5 km N Funk (40.621717°N, 99.2563°W). 24 June 2009. Keith Geluso. Verified by Curtis J. Schmidt, Sternberg Museum of Natural History, Hays, Kansas (MHP14708). First county record. Fills in distributional gap in south-central Nebraska between Dawson, Buffalo, Kearney, and Harlan counties (Fogell 2010, *op. cit.*). Individual was observed on road in agricultural area dominated by center-pivot irrigation. It specifically was captured in an area where the non-irrigated corners of the surrounding four center pivots came together.

KEITH GELUSO, Department of Biology, University of Nebraska at Kearney, Kearney, Nebraska 68849, USA; e-mail: gelusok1@unk.edu.

***TRACHYCEPHALUS ATLAS* (Bokermann's Casque-headed Treefrog)**. BRAZIL: PARAÍBA: Municipality of São João do Cariri: Olho D'água Farm (07.483333°S, 36.683333°W; WGS84). 13 March 2005. W. L. S. Vieira and G. G. Santana. Coleção Herpetológica do Departamento de Sistemática e Ecologia, Universidade Federal da Paraíba, João Pessoa, Paraíba, Brazil (UFPB 4887–4888). Verified by C. Arzabe. Previously known only from the type locality, Santo Onofre Farm, municipality of Maracas in Bahia State (Bokermann 1966. Neotropica 12[39]:210–124) and reserve Maurice Dantas and Exu in Pernambuco State (Borges-Nojosa and Santos 2005. Herpetofauna da área de Betânia e Floresta, Pernambuco. Ministério do Meio Ambiente, pp. 276–289). First state record extends known distribution 793 km from previously known locality. The specimens were collected as they called, floating in the water on a temporary pond in an area of Caatinga dry land vegetation during the early rainy season.

TESTUDINES — TURTLES

***CHRYSEMYS DORSALIS* (Southern Painted Turtle)**. USA: FLORIDA: Alachua Co.: Gainesville, Santa Fe College Northwest Campus (29.6827°N, 82.4353°W; WGS84; elev. 44 m). 25 June 2009. Matthew H. Kail. Verified by Kenneth L. Krysko. Florida Museum of Natural History (UF 159928). New county record. Female (straight midline carapace length = 112 mm, straight midline plastron length = 109 mm, mass = 205 g) captured by hand at edge of 0.2 ha pond.

MATTHEW H. KAIL, School of Veterinary Medicine, University of Florida, Gainesville, Florida 32611, USA (e-mail: snappergi@aol.com); **GERALD R. JOHNSTON**, Department of Natural Sciences, Santa Fe College, Gainesville, Florida 32606, USA (e-mail: jerry.johnston@sfcollege.edu); **ERIC SUAREZ**, Department of Wildlife Ecology and Conservation, University of Florida, Gainesville, Florida 32611, USA (e-mail: eric.suarez725@yahoo.com); **JOSEPH C. MITCHELL,** Mitchell Ecological Research Services, Gainesville, Florida 32627, USA (e-mail: dr.joe.mitchell@gmail.com).

***CHRYSEMYS PICTA* (Painted Turtle)**. USA: Clay Co.: 0.5 km N, 7.3 km W Fairfield (40.437467°N, 98.185683°W; NAD1983). 23 June 2009. Keith Geluso. Verified by Curtis J. Schmidt, Sternberg Museum of Natural History, Fort Hays State University, Hays, Kansas (MHP 14673). First county record. Fills in distributional

gap in south-central Nebraska (Ballinger et al. 2010. Amphibians and Reptiles of Nebraska. Rusty Lizard Press, Oro Valley, Arizona. 400 pp.; Fogell 2010. A Field Guide to the Amphibians and Reptiles of Nebraska. University of Nebraska, Lincoln. vi + 158 pp.). Observed crossing roadway surrounded by an agricultural field and a homestead.

KEITH GELUSO, Department of Biology, University of Nebraska at Kearney, Kearney, Nebraska 68849, USA; e-mail: gelusok1@unk.edu.

***GOPHERUS BERLANDIERI* (Texas Tortoise)**. MEXICO: COAHUILA: Municipality of Cuatro Ciénegas de Carranza: Área de Protección de Flora y Fauna Cuatrociénegas, 2 km SW of El Venado (26.8398861°N, 101.9587278°W; WGS84), 762 m elev. 29 August 2010. L. M. Coghill and J. Chávez-Campos. Verified by Luis Canseco Marquez. Colección Herpetológica del Museo de Zoología Alfonso L. Herrera, Facultad de Ciencias, UNAM (MZFC ID-014). First confirmed record for the Municipality of Cuatro Ciénegas de Carranza, extending the known distribution 53.4 km SW from the closest localities between Ciudad Hermanas and Monclova, Municipality of Abasolo (Lemos Espinal and Smith 2007. Amphibians and Reptiles of the State of Coahuila, Mexico. UNAM and CONABIO, México, D.F. xii + 550 pp.). A previous record, without voucher or locality information, reported this tortoise as a likely introduced species in the Área de Protección de Flora y Fauna Cuatrociénegas (McCoy 1984. J. Arizona-Nevada Acad. Sci. 19:49–59). We found multiple adult individuals of varying sizes and sexes in a single day crossing a road, suggesting an established population; a genetic study is needed to determine if the population is native or introduced. All were photographed, but not collected, because they were found in a protected area.

LYNDON M. COGHILL (e-mail: lcoghill@uno.edu) and **JOHEL CHAVES-CAMPOS** (e-mail: jchaves@uno.edu), Department of Biological Sciences, 2000 Lakeshore Drive, University of New Orleans, New Orleans, Louisiana 70148, USA; **URI OMAR GARCÍA VÁZQUEZ,** Laboratorio de Herpetología, Museo de Zoología, Departamento de Biología Evolutíva, Facultad de Ciencias, UNAM, A.P. 70-399, México, D.F. 04510 (e-mail: urigarcia@gmail.com); and **ARTURO CONTRERAS,** Acuario y Herpetario W. L. Minckley, Pte. Carranza 104, Nte., Cuatro Ciénegas de Carranza, Coahuila, México 27640 (e-mail: acuario_minckley@yahoo.com.mx).

***GOPHERUS POLYPHEMUS* (Gopher Tortoise)**. USA: FLORIDA: Collier Co.: Ten Thousand Islands. Fakahatchee Island (25.868°N, 81.496°W; NAD83) and Dismal Key (25.890°N, 81.560°W; NAD83) are located 11 and 17 km W of Everglades City, respectively, and approximately 2 km offshore. One adult shell and one live adult tortoise were observed near the western edge of Fakahatchee Island on 26 October 2010, and four adult tortoises and five active burrows were observed near the center of Dismal Key on 27 October 2010 by MTJ and LLW. Verified by J. Martinez. Harvard University, Museum of Comparative Zoology (MCZ R-188665; photo voucher).

These observations represent previously unknown coastal occurrences of Gopher Tortoise along the 100 km section of coast between Marco Island (Collier Co.) and Cape Sable (Monroe Co.) (e.g., Kushlan and Mazzotti 1984. J. Herpetol. 18[3]:231–239; Mushinsky and McCoy 1994. *In* Bury and Germano [eds.], Biology of North American Tortoises, pp. 39–47. National Biological Survey, Fish and Wildlife Research 13; NatureServe 2010. NatureServe Explorer: An Online Encyclopedia of Life. ver. 7.1. NatureServe, Arlington, Virginia. http://www.natureserve.org/explorer. Accessed 15 April 2011). Furthermore, these occurrences are worthy of note because Fakahatchee Island and Dismal Key are largely of anthropogenic origin, constructed by Native Americans (Calusa) prior to the 16th century. They are part of a series of large Calusa shell mounds distributed throughout the northern Ten Thousand Islands (Widmer 1988. The Evolution of the Calusa: A Nonagricultural Chiefdom of the Southwest Florida Coast. University of Alabama Press. Tuscaloosa, Alabama). Tortoises may occur on other large, isolated shell mounds between Marco Island and Cape Sable, although we have failed to detect tortoises or burrows on three other large shell mounds in the vicinity of Fakahatchee and Dismal: Four Brothers Key, Russell Key, and Sandfly Island. It is unknown whether these tortoises naturally colonized Fakahatchee Island and Dismal Key or were introduced there by Calusa or more recent (i.e., 19th-20th century) settlers.

These observations were made while conducting surveys for box turtles under a research permit from the National Park Service (Everglades National Park; EVER-2009-SCI-0038), a special use permit from the U.S. Fish and Wildlife Service (Ten Thousand Islands National Wildlife Refuge), research authorization from the Florida Department of Environmental Protection (Rookery Bay National Estuarine Research Reserve) and a scientific collection permit from the Florida Fish and Wildlife Conservation Commission (LSSC-10-00103).

***GRAPTEMYS PULCHRA* (Alabama Map Turtle)**. USA: GEORGIA: Floyd Co.: Numerous individuals of both sexes observed and photographed basking on logs in the Coosa River near Rome (34.20591°N, 85.29058°W; NAD83). 19 May 2011. John B. Jensen and Sean P. Graham. Verified by Jeffrey Lovich. AUM (AHAP-D 303–305, photographic vouchers). ALABAMA: Cherokee Co.: Weiss Reservoir (34.23245°N 85.52775°W; geo-referenced using Google Earth). 07 February 1970. John Chitwood. Verified by Craig Guyer. AUM 16654. These records partially fill a 200 km distribution gap between previous Coosa River drainage records upstream in the Oostanaula River in Gordon Co., Georgia (Santhuff and Wilson 1990. Herpetol. Rev. 21:39) and downstream in the Coosa River in Etowah Co., Alabama (Mount 1975. The Reptiles and Amphibians of Alabama. Auburn Univ. Agricult. Exp. Sta. 347 pp.). Additionally, both represent first county records (Mount 1975, *op. cit.*; Jensen et al. [eds.] 2008. Amphibians and Reptiles of Geórgia. Univ. of Georgia Press, Athens. 575 pp.), and the former also represents the first Georgia record from the Coosa River.

JENSEN**, Georgia Department of Natural Resources, Nongame Conservation Section, 116 Rum Creek Drive, Forsyth, Georgia 31029, USA (e-mail: john.jensen@gadnr.org); **SEAN P. GRAHAM**, Department of Biological Sciences, Auburn University, 331 Funchess Hall, Auburn University, Alabama 36849, USA (e-mail: grahasp@auburn.edu).

***HYDROMEDUSA TECTIFERA* (South American Snake-necked Turtle)**. BRAZIL: MINAS GERAIS: Municipality of São Roque de Minas: 20.569150°S, 45.567389°W (datum WGS 84), 937 m elev., area with typical cerrado vegetation. 2004. L. Eliege. Museu Nacional, Universidade Federal do Rio de Janeiro, Rio de Janeiro, RJ, Brazil (MNRJ19780). Verified by R. Fernandes. Species previously known from the states of São Paulo, Minas Gerais, Rio de Janeiro, Paraná, Santa Catarina, and Rio Grande do Sul, in Brazil; westward and southward through the Chaco, eastern Paraguay, and Formosa, northeastern Argentina, to Uruguay (Fritz and Havaš. 2007. Vert. Zool. 57[2]:149–368; Souza and Novelli 2009. Check List 5[3]:396–398), occurring in the basins of Paraná, Atlantic-Southeastern, Uruguay, and Atlantic Southern (Souza 2005. Rev. Esp. Herpetol. 19:33–46). Here we report the second record from the state of Minas Gerais, thus representing the second register for the Cerrado biome and in the São Francisco basin, extending its known distribution ca. 230 km NW from the first record in the state of Minas Gerais (Brazil, Minas Gerais, Ritápolis municipality; Souza and Novelli, *op. cit.*)

ANGELE DOS REIS MARTINS, Departamento de Vertebrados, Museu Nacional, Universidade Federal do Rio de Janeiro, Quinta da Boa Vista s/n, CEP 24940-040, Rio de Janeiro, Rio de Janeiro, Brazil (e-mail: angelemartins@gmail.com); **RAFAELLA DE CARVALHO GARBIN**, Instituto de Biologia, Universidade Federal do Rio de Janeiro, Av. SQUAMATA — LIZARDS

***ANADIA OCELLATA* (Ocellated Anadia)**. COLOMBIA: CÓRDOBA: Tierralta: Cerro Murrucucú, Parque Natural Nacional Paramillo, (8.3533°N, 76.395°W; Bogotá WGS 84; elev. 700 m). 05 April 2009. J. E. Carvajal-Cogollo. Collection of Reptiles of the Instituto de Ciencias Naturales, Universidad Nacional of Colombia, Bogotá D.C, Cundinamarca, Colombia (ICN 11868). Verified by O. V. Castaño-Mora, Rafael A. Moreno-Arias, and Guido Medina-Rangel. First country record. Extends species range approx. 300 linear km E in the Caribbean region of Colombia (Savage 2002. The Amphibians and Reptiles of Costa Rica. A Herpetofauna Between Two Continents, Between Two Seas. University of Chicago Press, Chicago, Illinois. 934 pp.). Species historically known from Costa Rica and western Panama (Oftedal 1974. Arq. Zool. 25[4]:203–265; Savage 2002, *op. cit.*). Specimen collected under Agreement No. 5, between the environmental authority-CVS-and Universidad Nacional de Colombia.

JUAN E. CARVAJAL-COGOLLO (e-mail: juancarvajalc@gmail.com), **VLADIMIR A. BERNAL-GONZÁLEZ** (e-mail: vlacho83@gmail.com), Grupo Biodiversidad y Conservación, Línea Reptiles, Instituto de Ciencias Naturales, Universidad Nacional de Colombia, Apartado 7495, Bogotá, D.C., Colombia; **NESTOR NONZOQUE-LÓPEZ,** Grupo SisBio, Museo de Historia Natural "Luis Gonzalo Andrade," Universidad Pedagógica y Tecnológica de Colombia-UPTC, Tunja-Colombia (e-mail: pocholope3@gmail.com).

***ANNIELLA PULCHRA* (California Legless Lizard)**. USA: CALIFORNIA: Kern Co.: SE slope Piute Mountains, Jawbone Canyon watershed, approx. 19.47 airline km WSW jct Jawbone Canyon Rd. x State Hwy 14 (35.29464°N, 118.20119°W; WGS84 datum; elev. 1255 m). 02 June 2010. L. E. Hunt. Verified by Paul Collins. Santa Barbara Museum of Natural History collection (SBMNH 2503). Second record for Piute Mountains. First occurrence and nearest record is from Kern Co., Green Spring, Kelso Valley (CAS 236208), 11.66 airline km to the NNW. Present specimen is an adult male found beneath a board on south-facing slope in open California Juniper-Interior Live Oak-Gray Pine woodland.

LAWRENCE E. HUNT, Hunt & Associates Biological Consulting Services, 5290 Overpass Road, Suite 108, Santa Barbara, California 93111, USA; e-mail: anniella@verizon.net.

***ASPIDOSCELIS TESSELATA* (Common Checkered Whiptail)**. USA: NEW MEXICO: Lea Co.: Wallach Quarry, 4.0 km E and 2.0 km N of NM 18/Wallach Lane (32.45412°N, 103.08113°W; NAD83/WGS84; elev.1054 m). 24 June 2008. Lea Co.: Eunice, 1100 Main St. (32.43690°N, 103.15932°W; NAD83/WGS84; elev. 1051 m). 27 June 2008. Don S. Sias, Ian W. Murray, and Jack C. Olson. Verified by J. Tomasz Giermakowski. University of New Mexico Museum of Southwestern Biology (MSB 75701, 75696). New county record (Degenhardt et al. 1996. Amphibians and Reptiles of New Mexico. Univ. New Mexico Press, Albuquerque. 431 pp.). An adult specimen was collected in the broken and rocky terrain of an active quarry surrounded by sandy shinoak habitat and mesquite grassland. An additional three animals were observed, and one collected, alongside a weed-grown wall outside of a building in downtown Eunice, NM. These animals might represent an introduced population, as this region is surrounded by expanses of unsuitable habitat. We caution that care be used when examining putative *A. tesselata* from regions where they may be sympatric

with *A. marmorata*. The only two specimens of '*A. tesselata*' recorded from Lea Co. (ENMU 1501, MSB 50698) were determined to be *A. marmorata* after examination of the supraorbital semicircles, dorsal pattern, a lack of abruptly enlarged mesoptychial scales, absence of spotting on the tail, and a bulging tail base.

***HEMIDACTLYUS FRENATUS* (Common House Gecko)**. HONDURAS: ISLAS DE LA BAHÍA: Roatán, inside and outside a private residence (16.406417°N, 86.3882°W; WGS84). 17 November 2010. Stesha A. Pasachnik. Verified by John Iverson. USNM Herp Images 2734–2736. First record for Roatan. Previously known from Islas de la Bahía only on Utila (McCranie et al. 2005. Amphibians & Reptiles of the Bay Islands and Cayos Cochinos, Honduras. Bibliomania, Salt Lake City, Utah. xii + 210 pp.). Many individuals of this species were observed throughout the island.

STESHA ANN PASACHNIK, Bay Islands Foundation, Roatán Branch, Islas de la Bahía, Honduras; e-mail: SAPasachnik@gmail.com.

***LEIOCEPHALUS CARINATUS* (Northern Curly-tailed Lizard)**. USA: FLORIDA: Osceola Co.: Kissimmee, 6000 West Osceola Parkway, Gaylord Palms Resort and Convention Center (28.34449°N, 81.52583°W, WGS 84; elev. 27 m). 29 May 2011. Rex Rowan. Verified by Kenneth L. Krysko. Florida Museum of Natural History (Photographic voucher UF 165483). Two or three individuals observed in the parking lot. New county record (Meshaka et al. 2004. The Exotic Amphibians and Reptiles of Florida. Krieger Publ. Co., Malabar, Florida. 155 pp.).

REX ROWAN, 2041 NE 15th Terrace, Gainesville, Florida 32609, USA; e–mail: rexrowan@gmail.com.

***SPHAERODACTYLUS ROSAURAE* (Bay Island Least Gecko)**. HONDURAS: ISLAS DE LA BAHÍA: Bay Islands Province: Cayos Chocinos, Cayo Cochino Pequeño, northeastern side of island (15.953069°N, 86.497667°W; WGS84), 1 m elev. 25 November 2010. J. A. Frazier. Verified by J. H. Townsend. MPM P750–51. First record for Cayo Cochino Pequeño. Even though it has not been recorded from Cayo Cochino Grande, it is known from throughout the Bay Islands area (McCranie et al. 2005. Amphibians and Reptiles of the Bay Islands and Cayos Cochinos, Honduras. Bibliomania, Salt Lake City, Utah. xii + 210 pp.). The lizard was found in coral skeleton rubble, ca. 3 m from high tide line.

We thank the Honduran Coral Reef Foundation and Operation Wallacea for supporting our research on the Cayos Cochinos.

***XANTUSIA WIGGINSI* (Wiggins' Desert Night Lizard)**. MÉXICO: BAJA CALIFORNIA SUR: Municipality of Mulegé, 46 km SW of San Ignacio (26.99164°N, 113.41670°W; WGS84), 10 m elev. 14 February 2009. Adam Backlin and Robert Fisher. Verified by Bradford D. Hollingsworth. Photographic Collection, San Diego Natural History Museum (SDNHM_HerpPC_05208–09). Southernmost record for this species in Baja California Sur, extending the known range 36 km SSW from Rancho San Ángel (Grismer 2002. Reptiles and Amphibians of Baja California: Including its Pacific Islands and the Islands in the Sea of Cortez. University California Press, Berkeley. xii + 399 pp.). This record also reduces the distributional gap between *X. wigginsi* and *X. sherbrookei* by 96 km (Bezy et al. 2008. J. Herpetol. 42:680–688). The lizard was found under the bark of a decomposing Cardon Cactus (*Pachycereus pringlei*).

ADAM R. BACKLIN (e-mail: abacklin@usgs.gov) and **ROBERT N. FISHER** (e-mail: rfisher@usgs.gov), US Geological Survey, Western Ecological Research Center, San Diego Field Station, 4165 Spruance Road, Suite 200, San Diego, California 92101, USA.

SQUAMATA — SNAKES

***AGKISTRODON PISCIVORUS* (Cottonmouth)**. USA: GEORGIA: Jeff Davis Co.: 4.3 km SE Denton (31.705298°N, 82.652605°W; NAD 83). 20 March 2011. B. Preston. Verified by Lance D. McBrayer. GSU 19001. New county record (Jensen et al. [eds.] 2008. The Amphibians and Reptiles of Georgia. University of Georgia Press, Athens. 575 pp.).

ROBERT PRESTON, JR., Office of Advancement, South Georgia College, 100 West College Park Drive, Douglas, Georgia 31533, USA; **DIRK J. STEVENSON**, The Orianne Society, Indigo Snake Initiative, 414 Club Drive, Hinesville, Georgia 31313, USA.

***AGKISTRODON PISCIVORUS PISCIVORUS* (Eastern Cottonmouth)**. USA: GEORGIA: Taylor Co.: Fall Line Sandhills Natural Area (32.578298°N, 84.269315°W; WGS 84.; elev. 206 m). 10 April 2011. Robert L. Hill. Verified by John Jensen. UTADC 6901–6902. New county record (Jensen et al. [eds.] 2008. Amphibians and Reptiles of Georgia, Univ. of Georgia Press, Athens. 575 pp.); previously documented in adjacent Crawford, Macon, and Marion counties. This species has been observed in Taylor County, but there were previously no vouchered specimens. Specimen observed swimming near center of a large ephemeral pond ~1.25 km N of Hwy 92 just after midnight, was moved to shore, photographed, and released.

ROBERT L. HILL, Department of Research and Conservation, Atlanta Botanical Garden, Atlanta, Georgia 30309, USA; e-mail: rhill@atlantabotanicalgarden.org.

ATRACTUS POTSCHI. BRAZIL: BAHIA: Municipality of Rio de Contas: Tapera Farm (13.517278°S, 41.901722°W; datum Córrego Alegre; 1200 m elev.). O. J. dos Santos. 10 November 2008 to 20 December 2009. Museu de Zoologia da Universidade Estadual de Santa Cruz, Ilhéus, Bahia (MZUESC 7929–7931). Verified by P. Passos. Species known form northeastern Brazil, from São Cristovão (11.016667°S, 37.200000°W) in the state of Sergipe southwestward to Poções (14.33333°S, 40.366667°W, 800 m. elev.) in the state of Bahia (Passos et al. 2010. Zootaxa 2364:1–63). These records in the Chapada Diamantina plateau extend the known range ca. 200 km NW from Poções and increases by 400 m the previous elevational limit (Passos et al., *op. cit.*).

***ATROPOIDES MEXICANUS* (Mexican Jumping Pitviper)**. PANAMÁ: COCLÉ: Omar Torrijos National Park (8.666667°N, 80.616667°W, WGS84; 718 m elev.). 2 October 2008. Julie M. Ray. Verified by Robert C. Jadin. UTADC 6814–15. First record for Coclé, with the closest known locality in Panamá being from Chiriquí Province to the west and Panamá Province to the east (Campbell and Lamar 2004. The Venomous Reptiles of the Western Hemisphere, Vol. I. Cornell Univ. Press, Ithaca, New York. xvii + 476 pp.). The snake was found on Los Helechos hiking trail, which is surrounded by mature secondary cloud forest.

JULIE M. RAY, La MICA Biological Station, El Copé de La Pintada, Coclé Province, Republic of Panamá; e-mail: julie.ray@lamica.org.

***BOA CONSTRICTOR* (Boa Constrictor)**. HONDURAS: SANTA BÁRBARA: 2 km E of San José de Colinas (15.033394°N, 88.283405°W, WGS84; 260 m elev.). 30 September 2010. James R. McCranie and Leonardo Valdés Orellana. Verified by Gustavo A. Cruz Díaz. UNAH 5640. First record for Santa Bárbara, with the closest known locality being ca. 30 km ESE at Agua Azul, Cortés (McCranie 2011. The Snakes of Honduras. Systematics, Distribution, and Conservation. Contrib. Hepetol. SSAR 26: x + 714 pp.).

The snake was killed by a local resident in an area of highly disturbed thorn scrub.

JAMES R. McCRANIE, 10770 SW 164th Street, Miami, Florida 33157–2933, USA (e-mail: jmccrani@bellsouth.net); **LEONARDO VALDÉS ORELLANA,** Gerente General de "Hondufauna," Investigador Privado, Colonia América, Bloque 9, Casa 1806, Comayagüela, MDC, Honduras (e-mail: leovalor@hotmail.com).

***COLUBER (=MASTICOPHIS) SCHOTTI* (Schott's Whipsnake)**. USA: TEXAS: Victoria Co.: ca. 200 m N of intersection of US Hwy 59, and Hwy 77 (28.7308°N, 97.0399°W). 04 April 2010. Thomas Sinclair, John Williams, and Scott Wahlberg. Verified by Travis J. LaDuc, Texas Natural History Collections (TNHC 83101 photo voucher). New county record, extends range NE from previous known limit (Dixon 2000. Amphibians and Reptiles of Texas. 2nd ed., revised. Texas A&M Univ. Press, College Station, Texas. 421 pp.). Under artificial cover in wooded area.

THOMAS A. SINCLAIR, 12903 Cloverwood Drive, Cypress, Texas 77429, USA (e-mail: tsinclair2@comcast.net); **JOHN T. WILLIAMS**, 12607 Orchard Summit Drive, Sugar Land, Texas 77498, USA; **SCOTT A. WAHLBERG,** 715 Martinsville Street, Nacogdoches, Texas 75961, USA.

***CROTALUS MOLOSSUS* (Blacktail Rattlesnake)**. MÉXICO: CHIHUAHUA: Municipio Nuevo Casas Grandes: Sierra La Escondida (30.52033333°N, 107.76716667°W, WGS84; 1583 m elev.). 21 August 2006. Ana Gatica-Colima. Verified by H. Gadsden-Esparza. Sección Herpetológica, Colección Científica de Vertebrados, Universidad Autónoma de Ciudad Juárez (CCV-UACJ 677–678). First record for the municipality and a ca. 48 km NE range extension from the nearest record in Chihuahua at Bosque near Rio Piedras Verdes, 1 km S Red Rock, Casas Grandes (Lemos Espinal et al. 2007. Anfibios y Reptiles del Estado de Chihuahua, México. UNAM-CONABIO, Tlanepantla, México, México. xiii + 613 pp.). Both male individuals were found during late morning, one on top of a rock and the other on the ground, in Chihuahuan Desert Scrub. Collecting permit (# 04660) was kindly issued by Dirección General de Vida Silvestre, SEMARNAT.

Matt Nordgren and Robert Villa. Verified by Eric N. Smith. UAZ 57310-PSV. New municipality record and a range extension of ca. 43 km NE of near Cinco de Mayo, ca. 5 mi. (8 km) W of Fed. Rt. 15, Municipality of Santiago Ixcuintla (MSB 10205). The snake was found DOR in tropical deciduous forest.

MATT NORDGREN, 1210 Thornwell Drive, Athens, Georgia 30606, USA (e-mail: happyherper@gmail.com); **ROBERT VILLA**, 811 N. 10th Ave., Tucson, Arizona 85705, USA (e-mail: cacabel1985@gmail.com).

***NERODIA ERYTHROGASTER TRANSVERSA* (Blotched Watersnake)**. USA: TEXAS: Hidalgo Co.: McAllen, along S. 10th St. (26.16473°N, 98.23066°W; WGS 84). 31 March 2011. José Manuel Cantú Martínez and Edwin Quintero. Verified by Frank W. Judd. University of Texas – Pan American Vertebrate Museum (UTPA 03116.) New county record (Dixon 2000. Amphibians and Reptiles of Texas. 2nd ed., revised. Univ. of Texas A&M Press, College Station, Texas. viii + 421 pp.; Werler and Dixon 2000. Texas Snakes: Identification, Distribution, and Natural History. University of Texas Press, Austin, Texas. xv + 437 pp.). Male (55.2 cm SVL, 68.0 cm TL, mass 211.3 g) found foraging in an irrigation ditch at 1818 h. Habitat consisted mostly of tall cattail reeds in shallow water roughly 30 cm deep.

A previous photographic record of *N. erythrogaster transversa* from Estero Llano Grande State Park (Weslaco, Hidalgo Co., 26.12634°N, 97.95649°W; WGS 84), approximately 28 km E from the McAllen record, was taken by CRH on 06 June 2009. A second male from Hidalgo Co., near Donna (26.09488°N, 98.07272°W; WGS 84), 18 km ESE from the McAllen record, was captured on 10 April 2011 by N. de la Cruz, J. Martinez, R. Silva, and M. Valdez. These observations fill a distributional gap in the Lower Rio Grande Valley between Starr Co. (63 km WNW of McAllen) and Cameron Co. (85 km ESE of McAllen).

JOSÉ MANUEL CANTÚ MARTÍNEZ, EDWIN QUINTERO, FREDERIC ZAIDAN III (e-mail: fzaidan@utpa.edu), Department of Biology and Center for Subtropical Studies, University of Texas – Pan American, 1201 West University Drive, Edinburg, Texas 78539, USA; **CHRISTOPHER R. HARRISON,** Department of Biology, Northwest Vista College, 3535 North Ellison Drive, San Antonio, Texas 78251, USA (e-mail: charrison34@alamo.edu).

***OPHEODRYS AESTIVUS* (Rough Greensnake)**. USA: GEORGIA: Wheeler Co.: 4.6 km SE of Scotland (32.029760°N, 82.774528°W; NAD 83). 7 April 2011. L. Wyrwich, D. Benboe, J. Godwin, and D. Stevenson. Verified by Lance D. McBrayer. GSU 18998. New county record (Jensen et al. [eds.] 2008. The Amphibians and Reptiles of Georgia. University of Georgia Press, Athens. 575 pp.).

STEVENSON**, The Orianne Society, Indigo Snake Initiative, 414 Club Drive, Hinesville, Georgia 31313, USA.

***OXYRHOPUS FORMOSUS* (Yellow-headed Calico Snake)**. COLOMBIA: CÓRDOBA: Tierralta: Cerro Murrucucú, Parque Natural Nacional Paramillo (8.3533°N, 76.395°W; Bogotá WGS 84; elev. 800 m). 03 March 2009. J. E. Carvajal-Cogollo and V. Bernal. ICN 10453, 11561. Verified by O. V. Castaño-Mora, Rafael A. Moreno-Arias, and Guido Medina-Rangel. New state record. Northernmost record for South America, extends range to Cordillera Occidental ca. 380 km airline N from nearest locality (Magdalena Valley, Department of Santander; Pérez-Santos and Moreno 1988. Ofidios de Colombia. Monografía VI. Mus. Reg. Sci. Nat. Torino. 517 pp.). Species was prevously known from Colombia, Venezuela, Ecuador, Peru, Guyana, Surinam, French Guiana, Brazil, Argentina, Bolivia (Uetz et al. 2011. http://reptile-database.org/, accessed 16 July 2011). In Colombia it has been recorded from the west of the Andes, in Eastern and Central Cordilleras (Pérez-Santos and Moreno 1988, *op. cit.*).

JUAN E. CARVAJAL-COGOLLO (e-mail: juancarvajalc@gmail.com), **VLADIMIR A. BERNAL-GONZÁLEZ** (e-mail: vlacho83@gmail.com), Grupo Biodiversidad y Conservación, Línea Reptiles, Instituto de Ciencias Naturales, Universidad Nacional de Colombia, Apartado 7495, Bogotá, D.C., Colombia; **NESTOR NONZOQUE-LÓPEZ,** Grupo SisBio, Museo de Historia Natural "Luis Gonzalo Andrade," Universidad Pedagógica y Tecnológica de Colombia-UPTC, Tunja-Colombia (e-mail: pocholope3@gmail.com).

***PANTHEROPHIS GUTTATUS* (Red Cornsnake)**. USA: GEORGIA: Calhoun Co.: 31.59013°N, 84.50880°W (WGS 84), elev. 73 m. 11 May 2011. Robert L. Hill and Leslie Phillips. Verified by John Jensen. UTADC 6903–6904. New county record (Jensen et al. [eds.], 2008. Amphibians and Reptiles of Georgia. Univ. of Georgia Press, Athens. 575 pp.); documented previously in adjacent Baker and Miller counties. Fresh DOR specimen observed at 2205 h on County Road 136, ~0.15 km S of jct with Hwy 234. Photographed and moved off road.

ROBERT L. HILL, Department of Research and Conservation, Atlanta Botanical Garden, Atlanta, Georgia 30309, USA; e-mail: rhill@atlantabotanicalgarden.org.

***PITUOPHIS MELANOLEUCUS* (Pinesnake)**. USA: ALABAMA: Macon Co.: DOR 75 m W of the intersection of State Road 14 and Macon County Rd. 77 (32.55921°N, 85.79234°W; WGS 84). 26 April 2011. S. Graham. AUM 39504. Verified by Craig Guyer. New county record (Mount 1975. The Reptiles and Amphibians of Alabama. Auburn Printing Co., Auburn, Alabama. 347 pp.). This record fills a ~50 km distribution gap for this species between the nearest specimens known from Tallapoosa Co. to the west and Russell Co. to the east. Like nearby specimens from Tallapoosa Co. (Mount, *op. cit.*), this specimen appears intergradient between *P. m. melanoleucus* and *P. m. mugitus*, having well-defined, black posterior blotches and a speckled anterior with no blotches.

SEAN P. GRAHAM, Auburn University Department of Biological Sciences, 331 Funchess Hall, Auburn, Alabama, USA; e-mail: grahasp@auburn.edu.

***RAMPHOTYPHLOPS BRAMINUS* (Brahminy Blind Snake)**. GABON: OGOOUÉ-MARITIME PROVINCE: Bendjé Department: Port-Gentil, Quartier SEEG. April 2008. P. Sarrazin. Institut Royal des Sciences naturelles de Belgique, Brussels (IRSNB 17969). Smithsonian Institution's Gabon Biodiversity Center, Gamba (Gamba 244). Verified by G. L. Lenglet (IRSNB). Both individuals found in cultivated house garden, where species reportedly is common according to local gardeners. First provincial record. This introduced species presently is known in Gabon from the capital city, Libreville, Estuaire Province and Port-Gentil (Pauwels et al. 2004. Hamadryad 29:138–139; Pauwels and Vande weghe 2008. Les reptiles du Gabon. Smithsonian Institution, Washington, D.C. 272 pp.). We thank G. L. Lenglet (IRSNB) for providing working facilities.

PAUWELS, Département des Vertébrés Récents, Institut Royal des Sciences naturelles de Belgique, Rue Vautier 29, 1000 Brussels, Belgium (e-mail: osgpauwels@yahoo.fr); **ELIE TOBI**, Smithsonian Institution, c/o Shell Gabon, BP 48, Gamba, Gabon (elie_tobi@yahoo.fr); **PHILIPPE SARRAZIN**, B.P. 1848, Port-Gentil, Gabon (e-mail: philippesarrazin@hotmail.fr).

***RAMPHOTYPHLOPS BRAMINUS* (Brahminy Blind Snake)**. CAPE VERDE: ISLAND OF SANTIAGO: Municipality of Santa Cruz:

Region of Achada Fazenda, Village of Zimbrão (15.061515°N, 23.626099°W). Late November 2009. Verified by Van Wallach. Florida Museum of Natural History, University of Florida. UF 157346, 157347. An invasive in many parts of Africa, particularly along coasts (Nussbaum 1980. Herpetologica 36[3]:215–221). Cape Verde, an archipelagic nation located ~500 km off west coast of Africa, has no native snakes (Heckman 1985. Environ. Mgmt. 9[2]:141–149). These specimens mark the first records of suborder Serpentes within the country. Two bricklayer's assistants located the specimens while cleaning around a house under construction (B. Nascimento, pers. comm.). Reports from Cape Verde indicated that farmers in Ribeira Zimbrão located two additional snakes in January 2010. We thank Jeff Lord for bringing these specimens to our attention.

KIRSTEN HECHT-KARDASZ (e-mail: kirstenkardasz@gmail.com), and **MAX A. NICKERSON** (e-mail: maxn@flmnh.ufl.edu), Florida Museum of Natural History, University of Florida, Gainesville, Florida 32611, USA.

***REGINA RIGIDA* (Glossy Crayfish Snake)**. USA: ARKANSAS: Calhoun Co.: 2 km N of Calion, Ouachita River backwaters off US 167; (33.346344°N, 92.532132°W). 01 April 2011. M. B. Connior. Verified by S. E. Trauth. Arkansas State University Museum of Zoology Herpetology Collection (ASUMZ 31641). New county record (Trauth et al. 2004. The Amphibians and Reptiles of Arkansas. University of Arkansas Press, Fayetteville. 421 pp.). Has also been collected in neighboring Union Co. This juvenile individual was hand-captured under a log in a small slough.

MATTHEW B. CONNIOR, Health and Natural Sciences, South Arkansas Community College, 300 S. West Avenue, El Dorado, Arkansas 71730, USA; e-mail: mconnior@southark.edu.

***STORERIA DEKAYI* (Dekay's Brownsnake)**. USA: GEORGIA: Effingham Co.: 12.0 km E Newington (32.579298°N, 81.375730°W; NAD 83). 2 February 2011. M. Elliott, D. Stevenson, and A. Day. Verified by Lance D. McBrayer. GSU 18999. New county record (Jensen et al. [eds.] 2008. The Amphibians and Reptiles of Georgia. University of Georgia Press, Athens. 575 pp.).

MATTHEW J. ELLIOTT, Georgia Department of Natural Resources Wildlife Resources Division, Nongame Conservation Section, 2065 US Hwy 278, SE, Social Circle, Georgia 30025, USA; **ANDY DAY** and **DIRK J. STEVENSON,** The Orianne Society, Indigo Snake Initiative, 414 Club Drive, Hinesville, Georgia 31313, USA.

***THAMNODYNASTES ALMAE* (Jararaca False Snake)**. BRAZIL: RIO GRANDE DO NORTE: Municipality of Santa Maria: Fazenda Tanques (5.854°S, 35.701°W; datum WGS84), elev. 137 m. 17 October 2009. J. da Silva Jorge. Coleção Herpetológica do Departamento de Botânica, Ecologia e Zoologia, Universidade Federal do Rio Grande do Norte, Natal, Rio Grande do Norte (CHBEZ 3044–3046). Verified by F. L. Franco. The species was known only in Brazil from Bahia, Ceará, Paraíba, Pernambuco, Alagoas and Bahia states (Franco and Ferreira 2002. Phyllomedusa 1:57–74; Guedes 2010 Herpetol. Rev. 41:245; Roberto et al. 2009. Herpetol. Rev. 40:238). New state record, extending range 250 km NW from the municipality of Cabaceiras, state of Paraíba, Brazil (Guedes 2010, *op. cit.*). All exemplars were collected in rupicolous bromeliads (*Encholirium spectabile*) in rock outcrops in Agreste region.

JAQUEIUTO S. JORGE (e-mail: queilto@yahoo.com.br) and **ELIZA M. X. FREIRE,** Laboratório de Herpetologia, Departamento de Botânica, Ecologia e Zoologia, Centro de Biociências, Universidade Federal do Rio Grande do Norte, Campus Universitário, Lagoa Nova, CEP 59072-970, Natal, Rio Grande do Norte, Brazil (e-mail: elizajuju@ufrnet.br).

***THAMNOPHIS BRACHYSTOMA* (Short-headed Gartersnake)**. USA: OHIO: Trumbull Co.: Brookfield Township, Masury. Sharon-Bedford Road, 0.576 km W of junction with State Line Road (41.20738°N; 80.52574°W; WGS 84). 27 July 2009, Raymond J. Novotny. Verified by Timothy O. Matson. Cleveland Museum of Natural History (CM 13425). New county record (Wynn and Moody 2006. Ohio Turtle, Lizard, and Snake Atlas. Ohio Biol. Surv. Misc. Contrib. No. 10). Previously, BSG and MAL confirmed a population of *T. brachystoma* in Mercer Co., Pennsylvania at the Pennsylvania-Ohio border 2.4 km N of Interstate 80 (41.20625°N; 80.51859°W; WGS 84). Voucher specimen deposited at the Natural History Museum at the Tom Ridge Environmental Center (TREC R-00053). This find led RJN to search for and subsequently discover the species in Trumbull Co., Ohio at a site 0.5 km W of the Pennsylvania site. Extends the range ca. 15 km N of nearest Ohio locality in Mahoning Co. (Novotny 1990. Herpetol. Rev. 21:42). These observations are approximately 36 km W of the nearest Pennsylvania records in Mercer Co. (Hulse et al. 2001. Amphibians and Reptiles in Pennsylvania and the Northeast. Cornell Univ. Press, Ithaca. xii + 419 pp.).

We thank Gian Rocco for alerting us to the presence of this population.

RAYMOND J. NOVOTNY, Ford Nature Center – Mill Creek MetroParks, 840 Old Furnace Road Youngstown, Ohio 44511, USA (e-mail; raynovotny@yahoo.com); **MARK A. LETHABY** (e-mail: mlethaby@verizon.net) and **BRIAN S. GRAY**, Natural History Museum at the Tom Ridge Environmental Center, 301 Peninsula Drive, Erie, Pennsylvania 16505, USA (e-mail: brachystoma@hotmail.com).

***THAMNOPHIS ELEGANS* (Terrestrial Gartersnake)**. USA: NEBRASKA: Banner Co.: 3 km S, 21 km W Harrisburg, Bull Canyon (41.52972°N, 103.9918°W; NAD 1983). 4 August 2010 and 19 September 2010. Keith Geluso and Kenneth N. Geluso. Verified by Curtis J. Schmidt. Sternberg Museum of Natural History, Fort Hays State University, Hays, Kansas (MHP 15627, 15625, respectively). First county records. Specimens represent a 100 km range extension to the south of localities in Sioux Co. (Ballinger et al. 2010. Amphibians and Reptiles of Nebraska. Rusty Lizard Press, Oro Valley, Arizona. 400 pp.; Fogell 2010. A Field Guide to the Amphibians and Reptiles of Nebraska. University of Nebraska, Lincoln. vi + 158 pp.). Individuals were captured along an intermittent stream on the floor of the canyon. Banks of the stream bed were grassy and shaded by Box Elders (*Acer negundo*). Steep slopes of canyonsides contained junipers (*Juniperus* sp.) and Ponderosa Pines (*Pinus ponderosa*).

KEITH GELUSO, Department of Biology, University of Nebraska at Kearney, Kearney, Nebraska 68849, USA (e-mail: gelusok1@unk.edu); **KENNETH N. GELUSO,** Department of Biology, University of Nebraska at Omaha, Omaha, Nebraska 68182, USA.

***THAMNOPHIS RADIX* (Plains Gartersnake)**. USA: ILLINOIS: Carroll Co.: Savanna, residence on the corner of Jefferson St. & 3rd St. (42.093380°N, 90.156288°W; WGS84). 23 May 2011. Collected by A. M. Durso. Verified by C. A. Phillips. INHS 2011-03. New county record (Phillips et al. 1999. Field Guide to Amphibians and Reptiles of Illinois. Illinois Natural History Survey Manual 8. 300 pp.). An adult female *T. radix* and three juveniles were discovered under paving stones in a residential garden in downtown Savanna.

ANDREW M. DURSO, Eastern Illinois University, Department of Biological Sciences, Charleston, Illinois 61920, USA; e-mail: amdurso@gmail.com.

The herpetofauna of Zacatecas is relatively poorly known judging by the few studies that have been published for the state. To date, 18 species of amphibians and 59 species of reptiles have been documented from Zacatecas (CONABIO 2006). Other papers listing species in Zacatecas include those by Smith and Taylor (1945, 1948, 1950), Baker et al. (1967), Wilson and McCranie (1979), and Baker et al. (1980). To help rectify this deficit in distributional information, we conducted field herpetological surveys in 2008 within the municipality of Atolinga, and during 2009 in the southern part of the state in the municipalities of Mezquital del Oro, Trinidad García de la Cadena, and Moyahua de Estrada (Fig. 1). Our collecting efforts produced nine new state and three new municipality records; all are presented herein. All voucher specimens and photographs were deposited in the Museo de Zoología, Facultad de Ciencias, UNAM (MZFC). All vouchers were collected by the first two authors and identifications verified by Luis Canseco Marquez. The map datum for locality coordinates was WGS84. Standard English names are those suggested by Liner and Casas-Andreu (2008).

ANURA — FROGS

***RHINELLA MARINA* (Cane Toad)**. Municipality of Mezquital Del Oro: 1 km N of Mezquital del Oro (21.22769°N, 103.37003°W), 1230 m elev. 19 April 2009. MZFC-ID 014. New state record and a ca. 56 km N range extension from closest reported locality north of Guadalajara, Jalisco (Ponce-Campos and Huerta-Ortega 2004). The toad was found in tropical deciduous forest.

***SMILISCA FODIENS* (Lowland Burrowing Treefrog)**. Municipality of García De La Cadena: 2 km S of García de la Cadena (21.18928°N, 103.47519°W), 1880 m elev. 31 August 2008. MZFC 23703. New state record, and a ca. 50 km NE (air line) range extension from the closet known locality at La Magdalena, Jalisco (Duellman 2001). This species was commonly observed under rocks in tropical deciduous forest.

***HYPOPACHUS VARIOLOSUS* (Sheep Frog)**. Municipality of Mezquital Del Oro: 1 km N of Mezquital del Oro (21.22769°N, 103.37003°W), 1230 m elev. 19 April 2009. MZFC 23716. Municipality of Atolinga, Ojo de Agua, 2 km W Los Adobes (21.74808°N, 103.49856°W), 2151 m elev. 28 July 2008. MZFC 23696. New state record, filling a distributional gap between localities at Guadalajara, Jalisco (Ponce-Campos and Huerta-Ortega 2004), and in the Municipality of Calvillo, Aguascalientes (Vásquez-Díaz and Quintero-Díaz 2005). The frogs were found in tropical deciduous forest and oak forest, respectively.

***LITHOBATES NEOVOLCANICUS* (Transverse Volcanic Leopard Frog)**. Municipality of García De La Cadena: 2 km S of García de la Cadena (21.19858°N, 103.47378°W), 1770 m elev. 31 August 2008. MZFC 23699. Municipality of Atolinga, Cerrito Pelón (21.82803°N, 103.41067°W), 2067 m elev. 26 October 2008. MZFC 23708. New state records, filling a distributional gap between localities north of Guadalajara, Jalisco (Ponce-Campos and Huerta-Ortega 2004), and in the Municipality of Calvillo, Aguascalientes (Vásquez-Díaz and Quintero-Díaz 2005). The frogs were found in grassland and aquatic vegetation, respectively.

***LITHOBATES PSILONOTA* (Smooth-backed Frog)**. Municipality of Mezquital Del Oro: 1 km N of Mezquital del Oro (21.22744°N, 103.16689°W), 1255 m elev. 17 May 2009. MZFC 23721. New state record, and a ca. 56 km N range extension from the closet known locality north of Guadalajara, Jalisco (Ponce-Campos and Huerta-Ortega 2004). It also fills a distributional gap between records in Aguascalientes and Jalisco (Hillis et al. 1984; Webb 2001). The frog was found in tropical deciduous forest near a water source.

SQUAMATA — LIZARDS

***CTENOSAURA PECTINATA* (Western Spiny-tailed Iguana)**. Municipality of Mezquital Del Oro: 1 km N Mezquital del Oro (21.22744°N, 103.16689°W), 1255 m elev. 17 May 2009. MZFC 23722. New municipality record. Previously known in Zacatecas from Santa Rosa, about 20 km (air line) to the northwest (Baker et al. 1967). The specimen was found in tropical deciduous forest.

***SCELOPORUS CLARKII* (Clark's Spiny Lizard)**. Municipality of Mezquital Del Oro: 1 km N of Mezquital del Oro (21.22769°N, 103.37003°W), 1230 m elev. 16 May 2009. MZFC 23719. New municipality record. Previously known in Zacatecas from Santa Rosa, about 20 km (air line) to the northwest (Baker et al. 1967). The specimen was found in tropical deciduous forest.

***SCELOPORUS UTIFORMIS* (Cope's Large-scaled Spiny Lizard)**. Municipality of Mezquital Del Oro: 1 km N of Mezquital del Oro (21.22769°N, 103.37003°W), 1230 m elev. 19 April 2009. MZFC 23717–718. New state record, with the closest previous known locality being from the Rio Santiago near Guadalajara, Jalisco (Ponce-Campos and Huerta-Ortega 2004). The specimen was found in tropical deciduous forest.

***UROSAURUS BICARINATUS* (Tropical Tree Lizard)**. Municipality of Atolinga: 3 km E of Cerrito Pelón (21.84442°N, 103.41564°W), 2120 m elev. 28 September 2008. MZFC 23705. New municipality record, and a range extension of ca. 73 km (air line) N of a

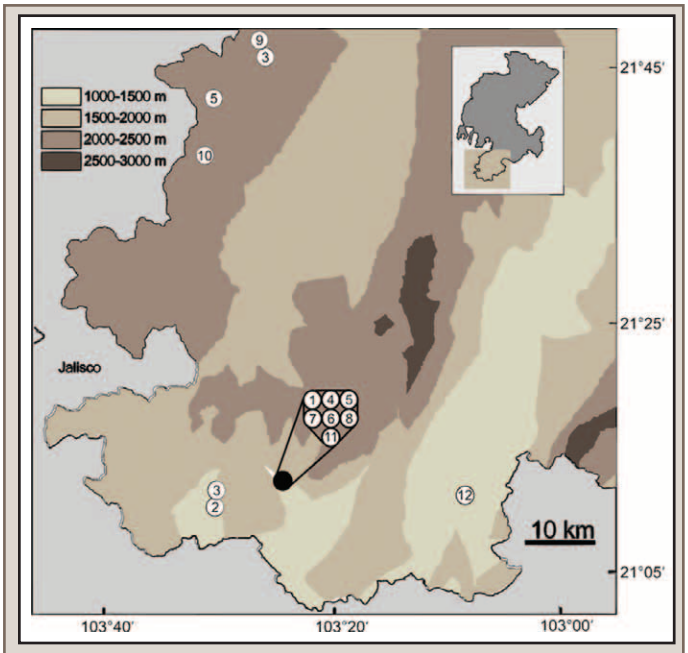

FIG. 1. Map of Zacatecas with localities of amphibians and reptiles reported herein: 1. *Rhinella marina* 2. *Smilisca fodiens* 3. *Lithobates neovolcanicus* 4. *Lithobates psilonota* 5. *Hypopachus variolosus* 6. *Ctenosaura pectinata* 7. *Sceloporus clarki* 8. *Sceloporus utiformis* 9. *Urosaurus bicarinatus* 10. *Lampropeltis mexicana* 11. *Leptodeira splendida* 12. *Crotalus basiliscus.*

previously known locality in the state at Santa Rosa (Baker et al. 1967). The specimen was found in oak forest.

SQUAMATA — SNAKES

***LAMPROPELTIS MEXICANA* (San Luis Potosí Kingsnake).** MUNICIPALITY OF ATOLINGA, LA CIENEGA: (21.66683°N, 103.51244°W), 2328 m elev. 29 September 2008. MZFC 23706. New state record, extending the known range in Zacatecas ca. 106 km SW from the closest known locality at Arroyo los Timones, 1 km S of Santa Rosa (Quintero-Díaz et al. 2001), and fills an east-west gap between the known localities in Aguascalientes (Vásquez-Díaz and Quintero-Díaz, 2005) and Nayarit (Hansen et al. 2011). The snake was found in oak forest.

***LEPTODEIRA SPLENDIDA* (Splendid Cat-eyed Snake).** MUNICIPALITY OF MEZQUITAL DEL ORO: 1 km N of Mezquital del Oro (21.22744°N, 103.16689°W), 1255 m elev. 17 May 2009. MZFC 23723. New state record, extending the known range ca. 42 km N from the closet known locality north of Guadalajara, Jalisco (Ponce-Campos et al. 2003). The specimen was found in tropical deciduous forest.

***CROTALUS BASILISCUS* (Mexican West Coast Rattlesnake).** MUNICIPALITY OF MOYAHUA DE ESTRADA: 2.25 km N (by road) of Santa Rosa (21.21256°N, 103.18183°W), 1148 m elev. 7 August 2009. MZFC-ID 013. New state record, with the closest known locality being 102 km S from Rio Santiago in Guadalajara, Jalisco (Ponce-Campos and. Huerta-Ortega 2004). The specimen was found in tropical deciduous forest.

New and Noteworthy Records of Amphibians and Reptiles from Reserva de la Biósfera Bosawas, Nicaragua

Nicaragua has a diverse herpetofauna (Köhler 2001; Sunyer and Köhler 2010) that, until recently, has been relatively neglected by researchers when compared to its neighboring countries, Costa Rica (Sasa et al. 2010; Savage 2002) and Honduras (McCranie and Wilson 2002; Townsend and Wilson 2010). As the largest country in Central America, Nicaragua's herpetofaunal diversity is still one of the least known in the region, due largely to the inaccessibility of many areas, particularly along the Atlantic versant. Recent herpetological studies have targeted these inaccessible areas and our knowledge of the Nicaraguan herpetofauna has grown considerably ever since (Köhler 2001; Köhler et al. 2004; Köhler and Sunyer 2006; Sunyer and Köhler 2007, 2010; Sunyer et al. 2008a, 2009a, 2009b, 2010). Among these under-surveyed regions is the largest protected area in the country, Reserva de la Biósfera Bosawas (Bosawas). Covering a total area of 19,926 km^2, roughly 16.5% the total land area in the country, Bosawas is situated in north-central Nicaragua within the departments of Jinotega and Región Autónoma del Atlántico Norte (Atlántico Norte) (MARENA 2009). In addition to vast expanses of primary lowland broadleaf rainforest, Bosawas contains several intact cloud forests and is part of the southern end of the Nuclear Central American highlands. Five of these highland sites lying within the boundary of Bosawas have also been delineated protected areas: Parque Nacional Saslaya, Reserva Natural Cerro Kilambé, Reserva Natural Macizos de Peñas Blancas, Reserva Natural Cerro Banacruz, and Reserva Natural Cerro Cola Blanca (MARENA 2009).

While conducting surveys throughout Bosawas from June 2007 through October 2008, we documented 38 new departmental records, and several other noteworthy accounts of amphibians and reptiles that were poorly known within Nicaragua, reported herein. All specimens were verified by Sebastian Lotzkat and Robert Lara. Voucher specimens were deposited in the Florida Museum of Natural History (UF), Senckenberg Forschungsinstitut und Naturmuseum (SMF), or Museo Herpetológico de la UNAN-Leon (MHUL). Departmental and other records were confirmed using locality information summarized in Köhler and Seipp (1998), Köhler (2001), Köhler et al. (2004), Sunyer and Köhler (2007), Sunyer et al. (2009a), or in other references cited in the text. Geocoordinates are based on datum WGS84.

ANURA — FROGS

AGALYCHNIS SALTATOR. JINOTEGA: Siwi Was (14.383407°N, 84.966888°W), 180 m elev. 30 July 2007. S. L. Travers, R. Picado, J. F. López, and S. Charley. UF 156023. New departmental record and only the third from Nicaragua, with the closest one being from Eden Mine and Siuna, Department of Atlántico Norte (Duellman 2001; King et al. 2007). The frog was sitting on a tree leaf at 2005 h, 2 m above forest floor.

CRAUGASTOR LAURASTER. JINOTEGA: Reserva Natural Cerro Kilambé, El Chiflón (13.5781°N, 85.707967°W), 1540 m elev. 5 October 2008. S. L. Travers, L. A. Obando, A. Velasquez, J. Lumbi, N. Lumbi, J. S. Lumbi, and A. Zelaya. UF 156037. New departmental record and slight upward elevational extension of 5 m (Sunyer and Köhler 2010). It is also known from the adjacent Nicaraguan departments of Matagalpa and Estelí (Köhler 2001). Atlántico Norte: Parque Nacional Saslaya, Campamento Pie Saslaya (13.76825°N, 85.024483°W), 1200 m elev. 3 July 2007. S. L. Travers, J. Sunyer, L. A. Obando, and O. Montalván. UF 156038. New departmental record.

CRAUGASTOR MIMUS. JINOTEGA: Reserva Natural Cerro Kilambé, Campamento Oedipina (13.574567°N, 85.696817°W), 1626 m elev. 16 July 2008. S. L. Travers, L. A. Obando, S. Doucette-Riise, A. Velasquez, M. Lumbi, I. Arauz, A. Zelaya, and M. Arauz. UF 156031. This record extends the known elevational range of this species by 686 m (Savage 2002).

HYPOPACHUS VARIOLOSUS. JINOTEGA: Reserva Natural Cerro Kilambé, La Escuelita (13.619633°N, 85.723317°W), 1070 m elev. 19 July 2008. S. L. Travers, L. A. Obando, S. Doucette-Riise, A. Velasquez, A. Zelaya, and M. Arauz. UF 156020. New departmental record. The frog was found dead at 1615 h on a dirt road.

INCILIUS COCCIFER. JINOTEGA: Wiwilí (13.62375°N, 85.798633°W), 353 m elev. 13 July 2008. S. L. Travers, L. A. Obando, and S. Doucette-Riise. UF 156022. New departmental record. The toad was found calling at 2000 h from a puddle in a cattle pasture.

INCILIUS CONIFERUS. JINOTEGA: Siwi Was (14.387767°N, 84.979917°W), 180 m elev. 29 July 2007. S. L. Travers, R. Picado, J. F. López, and S. Charley. UF 156033. Northernmost record for the species in Central America, extending its range 118 km NE from Cerro Kilambé, El Hielo, Jinotega (Köhler 2001). The toad was found active on a palm frond at 2030 h, 1 m above forest floor.

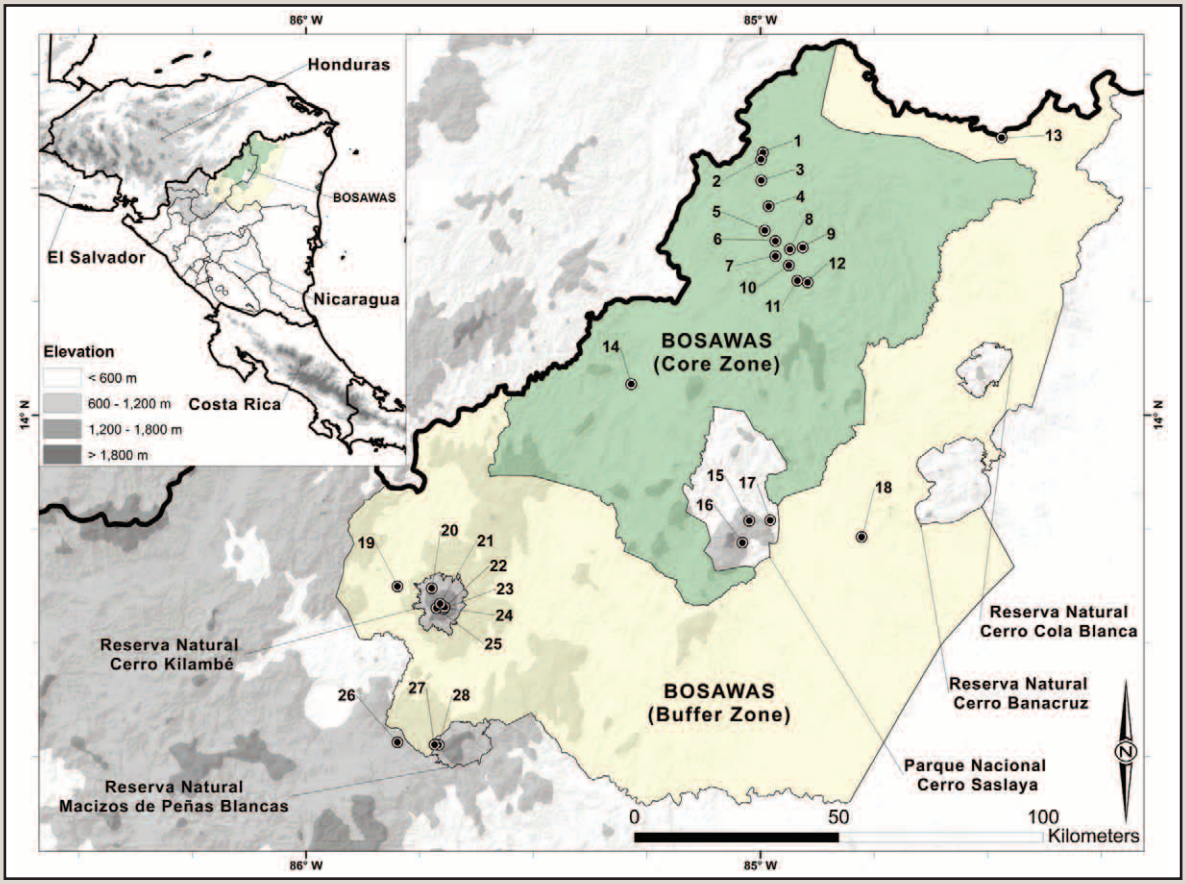

FIG. 1. Map of Reserva de la Biósfera Bosawas, Nicaragua. Numbers correspond to the following collection localities: Limi Tingni (1), Wailahka (2), Aran Dak (3), Supa Was (4), Maikawana (5), Siwi Was (6), Muru Ta (7), Pamka Buhna (8), Laka Papan (9), Kulum Kitang (10), Urus Was (11), Kama Pih (12), Krin Krin (13), Río Bocay near Amak (14), Campamento Pie Saslaya (15), El Revenido (16), Río Majagüe (17), Siuna (18), Wiwilí (19), La Escuelita (20), property of A. Velasquez (21), La Reculona (22), Campamento Oedipina (23), El Chiflón (24), El Desacuerdo (25), La Cascada (26), El Horno (27), El Fogón (28).

SMILISCA PHAEOTA. JINOTEGA: Reserva Natural Cerro Kilambé, La Reculona (13.5781°N, 85.69495°W), 1457 m elev. 15 July 2008. S. L. Travers, L. A. Obando, S. Doucette-Riise, A. Velasquez, M. Lumbi, and I. Arauz. UF 156034. New elevational record extending the range of the species upward by 207 m (Köhler 2001).

SMILISCA SORDIDA. JINOTEGA: Supa Was (14.4599°N, 84.981867°W), 175 m elev. 24 August 2008. S. L. Travers, D. Manzanarez, R. Picado, J. F. López, and S. Charley. UF 156323. New departmental record that fills in a distributional gap of 210 km between the northernmost Nicaraguan record (Duellman 2001) and the nearest known locality in Honduras (McCranie et al. 2006). The frog was active at 2054 h on tree branch, 8 m above forest floor.

TERATOHYLA PULVERATA. ATLÁNTICO NORTE: Laka Papan (14.369467°N, 84.906983°W), 220 m elev. 18 August 2008. S. L. Travers, D. Manzanarez, R. Picado, J. F. López, and S. Charley. UF 156029. New departmental record for this species (Köhler 2001) that was previously known only from three localities in Nicaragua (Köhler 2001; Sunyer et al. 2009a).

TERATOHYLA SPINOSA. ATLÁNTICO NORTE: Kama Pih (14.292533°N, 84.896067°W), 250 m elev. 26 July 2007. S. L. Travers, R. Picado, J. F. López, and S. Charley. UF 156012. New departmental record. The frog was calling from a tree branch at 1920 h, 1.3 m above a stream. Jinotega: Supa Was (14.4599°N, 84.981867°W), 175 m elev. 24 August 2008. S. L. Travers, R. Picado, J. F. López, and S. Charley. UF 156030, 156035. New departmental records. The amplexing pair was found on a leaf at 2040 h, 4 m above a stream. *Teratohyla spinosa* inhabits humid lowlands from eastern Honduras to northwestern Ecuador (McCranie and Wilson 2002; Savage 2002) and was only recently documented in Nicaragua (Sunyer and Köhler 2007). Our records fill in a previous distributional gap of 412 km between the northernmost Nicaraguan record (Sunyer and Köhler 2007) and the nearest known locality in Honduras (McCranie et al. 2006).

SQUAMATA — LIZARDS

ANOLIS BIPORCATUS. JINOTEGA: Reserva Natural Cerro Kilambé, on property of A. Velasquez (13.585583°N, 85.70485°W), 1300 m elev. 4 October 2008. S. L. Travers, L. A. Obando, and J. Lumbi. UF 156021. New departmental record.

ANOLIS CAPITO. JINOTEGA: Reserva Natural Macizos de Peñas Blancas, El Fogón (13.27498°N, 85.708067°W), 1405 m elev. 23 October 2008. S. L. Travers, L. A. Obando, and B. Alemán. UF 156024. New elevational record, extending its range upward by 105 m (Köhler 2001; Savage 2002).

ANOLIS CARPENTERI. JINOTEGA: Reserva Natural Macizos de Peñas Blancas, La Cascada (13.275783°N, 85.716967°W), 1058 m elev. 20 October 2008. S. L. Travers, L. A. Obando, and B. Alemán. UF 156032. New departmental record.

ANOLIS WERMUTHI. JINOTEGA: Reserva Natural Cerro Kilambé, El Desacuerdo (13.575917°N, 85.71285°W), 1658 m elev. 6 October 2008. S. L. Travers, L. A. Obando, A. Velasquez, J. Lumbi, M. Lumbi, J. S. Lumbi, and A. Zelaya. UF 156025. New elevational record, extending its upward range by 158 m (Köhler 2001; Sunyer et al. 2008b). Reserva Natural Macizos de Peñas Blancas, El Horno (13.280867°N, 85.7987°W), 1516 m elev. 24 October 2008. S. L. Travers and L. A. Obando. UF 156026. This site corresponds to the fifth known isolated population of *A. wermuthi*, all of which are within Nicaragua (Sunyer et al. 2008b).

HEMIDACTYLUS FRENATUS. ATLÁNTICO NORTE: Siuna (13.732483°N, 84.777217°W), 204 m elev. 28 July 2008. S. L. Travers, S. Doucette-Riise, and S. C. Gonzalez. UF 156028. New departmental record. The closest known locality in Nicaragua is from Rama, located 185 km southeast in the Department of Atlántico Sur (Köhler 2001). *Hemidactylus frenatus* is a non-native species in Nicaragua, and although poorly documented, it occurs in most developed areas throughout the country.

SPHAERODACTYLUS MILLEPUNCTATUS. JINOTEGA: Kulum Kitang (14.33°N, 84.9375°W), 180 m elev. 18 June 2007. S. L. Travers, J. H. Townsend, L. D Wilson, J. Sunyer, L. A. Obando, D. E. Griffith, R. Picado, J. F. López, and S. Charley. SMF 88137. New departmental record.

SPHENOMORPHUS CHERRIEI. JINOTEGA: Limi Tingni (14.578017°N, 84.994283°W), 139 m elev. 30 August 2008. S. L. Travers, D. Manzanarez, R. Picado, J. F. López, and S. Charley. UF 156027. New departmental record.

SQUAMATA — SNAKES

BOA CONSTRICTOR. JINOTEGA: Río Bocay near Amak (14.0688°N, 85.2843°W), 208 m elev. 9 June 2007. S. L. Travers, J. H. Townsend, L. D Wilson, J. Sunyer, L. A. Obando, and D. E. Griffith. SMF 89012. New departmental record. The snake was resting on vegetation at 1200 h, 1 m above a river.

CHIRONIUS GRANDISQUAMIS. JINOTEGA: Aran Dak (14.516883°N, 84.997983°W), 153 m elev. 14 August 2008. S. L. Travers, D. Manzanarez, R. Picado, J. F. López, and S. Charley. UF 155963. New departmental record. The snake was found sleeping on vegetation at 2100 h, 3 m above a stream.

CLELIA CLELIA. JINOTEGA: Maikawana (14.406733°N, 84.990383°W), 160 m elev. 14 July 2007. S. L. Travers, R. Picado, J. F. López, and S. Charley. UF 156002. New departmental record. The snake was found while active at 2000 h, on forest floor after heavy rains.

CORALLUS ANNULATUS. ATLÁNTICO NORTE: Pamka Buhna (14.365333°N, 84.93495°W), 186 m elev. 20 August 2008. S. L. Travers, D. Manzanarez, R. Picado, J. F. López, and S. Charley. UF 155940. New departmental record. This report represents the fourth known locality for Nicaragua that fills in a distributional gap of 290 km between the northernmost Nicaraguan record (Gaige et al. 1937) and the nearest known site in Honduras (McCranie et al. 2006). The snake was active on tree branch at 2040 h, 1.5 m above a stream.

DENDROPHIDION PERCARINATUM. JINOTEGA: Aran Dak (14.516883°N, 84.997983°W), 153 m elev. 14 August 2008. S. L. Travers, D. Manzanarez, R. Picado, J. F. López, and S. Charley. UF 155978. New departmental record. The snake was found sleeping on vegetation at 2130 h, 1 m above forest floor.

DENDROPHIDION VINITOR. JINOTEGA: Reserva Natural Cerro Kilambé, on property of A. Velasquez (13.585583°N, 85.70485°W), 1300 m elev. 5 October 2008. S. L. Travers, L. A. Obando, and J. Lumbi. UF 155977. New departmental record. The snake was brought to us by a local farmer who had recently killed it in a coffee plantation at ca. 1000 h.

DIPSAS BICOLOR. ATLÁNTICO NORTE: Kama Pih (14.292533°N, 84.896067°W), 250 m elev. 25 July 2007. S. L. Travers, R. Picado, J. F. López, S. Charley, and J. L. Henry. UF 155965. New departmental record. It was uncovered from inside of a hollow log at 0940 h, on forest floor. JINOTEGA: Supa Was (14.4599°N, 84.981867°W), 175 m elev. 24 August 2008. S. L. Travers, D. Manzanarez, R. Picado, J. F. López, and S. Charley. UF 155967. New departmental record. The snake was active on a tree branch at 2010 h, 4 m above ground. In Nicaragua the species was most recently known only from the holotype and type locality, 320 km S of the Atlántico Norte location at Chontales Mines, in the Department of Río San Juan (Günther 1895 [1885–1902]). Thus, our two specimens also represent the second and third records for the country (Köhler 2001).

DRYMARCHON MELANURUS. JINOTEGA: Muru Ta (14.350275°N, 84.966822°W), 180 m elev. 13 June 2007. S. L. Travers, J. H. Townsend, L. D Wilson, J. Sunyer, L. A. Obando, D. E. Griffith, R. Picado, J. F. López, and S. Charley. SMF 89016. New departmental record. The snake was detected along a riverbank while in the process of consuming an adult *Leptodactylus savagei*.

ENULIOPHIS SCLATERI. JINOTEGA: Muru Ta (14.3665°N, 84.976°W), 180 m elev. 15 July 2007. S. L. Travers, R. Picado, J. F. López, and S. Charley. UF 155949. New departmental record and only the fourth individual reported from Nicaragua (Köhler et al. 2004). The snake was emerging from a tree hole at 2100 h, 1 m above the forest floor.

IMANTODES INORNATUS. JINOTEGA: Wailahka (14.563233°N, 84.998533°W), 120 m elev. 6 August 2007. S. L. Travers, R. Picado, J. F. López, and S. Charley. UF 155943. New departmental record. This individual represents the third country record for this species from Nicaragua (Köhler 2001). It was active on tree branch at 2020 h, 2 m above forest floor.

LEPTODEIRA SEPTENTRIONALIS. ATLÁNTICO NORTE: Parque Nacional Saslaya, Río Majagüe (13.769233°N, 84.978567°W), 220 m elev. 30 June 2007. S. L. Travers, J. Sunyer, L. A. Obando, and O. Montalván. SMF 88980. New departmental record. The closest known locality in Nicaragua is located 124 km to the southwest at Finca Tepeyac, Department Matagalpa (Köhler 2001). The snake was found on branch at 2121 h, 2.5 m above forest floor.

MASTIGODRYAS MELANOLOMUS. JINOTEGA: Reserva Natural Cerro Kilambé, trail from La Escuelita to a property owned by A.

Velasquez (13.5943°N, 85.696817°W), 1178 m elev. 14 July 2008. S. L. Travers, L. A. Obando, and S. Doucette-Riise. UF 155990. New departmental record. The snake was found resting on vegetation at 1100 h, 1.2 m above trail.

OXYBELIS BREVIROSTRIS. JINOTEGA: Siwi Was (14.38776°N, 84.979917°W), 180 m. 30 July 2007. S. L. Travers, R. Picado, J. F. López, and S. Charley. UF 155922. New departmental record. The snake was sleeping on a tree branch at 2020 h, 2 m above forest floor.

PORTHIDIUM NASUTUM. JINOTEGA: Aran Dak (14.516883°N, 84.997983°W), 153 m elev. 4 August 2007. S. L. Travers, R. Picado, J. F. López, and S. Charley. MHUL 001. New departmental record. This specimen was brought in by one of the villagers who had killed it in secondary broadleaf forests outside the immediate vicinity of the community.

SIBON LONGIFRENIS. JINOTEGA: Kulum Kitang (14.33°N, 84.9375°W), 180 m elev. 18 June 2007. S. L. Travers, J. H. Townsend, L. D Wilson, J. Sunyer, L. A. Obando, D. E. Griffith, R. Picado, J. F. López, and S. Charley. SMF 88182. ATLÁNTICO NORTE: Urus Was (14.296217°N, 84.918517°W), 220 m elev. 19 July 2007. S. L Travers, R. Picado, J. F. López, and S. Charley. UF 155952. Both are new departmental records, representing the second and third localities known from Nicaraugua that fill a 490 km distributional gap between the Isla de Diamante on the San Juan River (Department of San Juan) near the Costa Rican border (Köhler 2001) and the nearest locality in Honduras (McCranie et al. 2006).

SIBON NEBULATUS. JINOTEGA: Wailahka (14563233°N, 84.998533°W), 120 m elev. 7 August 2007. S. L. Travers, R. Picado, J. F. López, and S. Charley. UF 155959. New departmental record. The snake was brought in this morning by a villager who had caught it the previous night as it crawled through his thatched-roof stilt house.

SPILOTES PULLATUS. JINOTEGA: Wailahka (14.563233°N, 84.998533°W), 120 m elev. 6 August 2007. S. L. Travers, R. Picado, J. F. López, and S. Charley. UF 155950. New departmental record.

TRETANORHINUS NIGROLUTEUS. JINOTEGA: Muru Ta (14.3665°N, 84.976°W), 180 m elev. 13 June 2007. S. L. Travers, J. H. Townsend, L. D. Wilson, J. Sunyer, L. A. Obando, D. E. Griffith, R. Picado, J. F. López, and S. Charley. SMF 87266. ATLÁNTICO NORTE: Laka Papan (14.369467°N, 84.906983°W), 220 m elev. 17 August 2008. S. L. Travers, D. Manzanarez, R. Picado, J. F. López, and S. Charley. UF 155979; Krin Krin (14.61115°N, 84.469167°W), 60 m elev. 16 August 2007. J. Sunyer and D. Manzanarez. MHUL 002. All the above are new departmental records. Villa (1970) provided a point locality map of *T. nigroluteus* that appeared to contain a record from northeastern Nicaragua. However, we are hesitant to consider this a confirmed record from Atlántico Norte because it is not supported by a voucher specimen or any matching locality information.

TROPIDODIPSAS SARTORII. ATLÁNTICO NORTE: Parque Nacional Saslaya, El Revenido (13.719933°N, 85.039633°W), 793 m elev. 1 August 2008. S. L. Travers, S. Doucette-Riise, S. C. Gonzalez, A. Baldonado, and I. Cruz. UF 155945. New departmental record. The snake represents the second country record that bridges a distributional gap between the other site located 240 m southwest at Casa Colorada, Las Nubes, Department of Managua (Köhler 2001; Villa 1971) and Arunta Tingni Kiamp, Department of Gracias a Dios, Honduras, which is located 135 km to the north. This is also the first record for the Atlantic versant of Nicaragua, and the southernmost record for its Atlantic slope distribution in Mesoamerica. The snake was found active on forest floor at 2152 h.

TESTUDINES — TURTLES

KINOSTERNON LEUCOSTOMUM. JINOTEGA: Siwi Was (14.387767°N, 84.97991°W), 180 m elev. 30 July 2007. S. L. Travers, R. Picado, J. F. López, and S. Charley. UF 156320. New departmental record. The turtle was found swimming in a stream that was ca. 2 m wide, at 2020 h.

TRACHEMYS VENUSTA. JINOTEGA: Rio Lakus, between Aran Dak and Muru Ta (14.416667°N, 84.966667°W), 160 m elev. 12 June 2007. S. L. Travers, J. H. Townsend, L. D Wilson, J. Sunyer, L. A. Obando, D. E. Griffith, R. Picado, J. F. López, and S. Charley. SMF 88199. New departmental record. The closest known locality for this species in Nicaragua is 130 km southeast at Alamikamba, Department Atlántico Norte (Köhler 2001).

Acknowledgments.—Collecting and exportation permits were provided by R. Montoya, F. Gadea, R. Salvador, J. Aristhomene, I. Ortega, L. Díaz, C. R. Mejía, and A. Lorío, Ministerio del Ambiente y los Recursos Naturales (MARENA), Managua, Nicaragua. Indigenous permits were provided by M. Serapio, KUNASPAWA/Regimen Especial Alto Wanki y Bokay. New County Records from Grundy County, Tennessee on the Mid-Cumberland Plateau of Southern Tennessee, USA

The southeastern United States is known for its high herpetofaunal diversity, which can be partly explained by high habitat diversity (Bailey et al. 2006). However, there are still many areas within the southeast that are not well studied, with little scientific documentation of species composition. One such area is the mid-Cumberland Plateau, in particular Grundy Co., Tennessee. Previous documentations for the area can be found in Anderson and Tilley (2003), Fontanella et al. (2008), Miller and Niemiller (2007), Miller et al. (2005) and Williams (1988). However, most of these reports dealt with a single species. Miller et al. (2005) provided the most extensive documentation of species composition in and around Grundy Co..

We implemented a research project addressing herpetofaunal response to oak-regenerating silviculture treatments in 2009–2010. We detected a total of 33 species and 11 are declared new county records. All records were deposited as photographic vouchers in Austin Peay State University (APSU) David H. Snyder Museum of Zoology. All verified by Arthur F. Scott. Along with verification by A. Scott, all specimens were referenced for accuracy by checking Redmond and Scott (1996) and Scott and Redmond (2008). Nomenclature and standard English names follow those used in Crother (2008). Locality coordinates are in decimal degrees in NAD83 UTM zone 16N.

NATURAL HISTORY NOTES

CAUDATA — SALAMANDERS

***AMBYSTOMA OPACUM* (Marbled Salamander). SHREW PREDATION.** Laboratory studies demonstrate that ambystomatid salamanders have behavioral and chemical defenses against Northern Short-tailed Shrew (*Blarina brevicauda*) predation (Brodie et al. 1979. Copeia 1979:270–274). Nonetheless, indirect observations made during radio-telemetry studies of free-ranging Spotted Salamanders (*Ambystoma maculatum*) and Tiger Salamanders (*Ambystoma tigrinum*) indicate that Northern Short-tailed Shrews can overcome these defenses and prey upon ambystomatids in subterranean tunnels (Madison 1997. J. Herpetol. 31:542–551; Madison and Farrand 1998. Copeia 1998:402–410). Herein, I provide a direct observation of a Southeastern Short-tailed Shrew (*Blarina carolinensis*) attacking and presumably killing a post-ovipositional adult female Marbled Salamander (*Ambystoma opacum*).

Observations began at 1147 h, 7 Nov 2010, when I heard a rustle in the leaf litter along the elevated boardwalk in Congaree National Park, Richland Co., South Carolina, USA. I observed the salamander moving quickly across the top of the leaf litter. Within seconds, the shrew emerged from the leaf litter and quickly and repeatedly bit the salamander's back and tail. After the attack, the shrew retreated and the salamander resumed crawling across the leaf litter. The shrew, always moving beneath the leaf litter, repeatedly emerged to briefly attack the salamander, and then retreat beneath the leaves. In addition to quick bites, the shrew also latched onto the salamander's back or tail with its mouth and dragged the salamander backwards several cm. When grabbed on the back by the shrew, the salamander assumed a rigid posture, coiling its body and tail towards the shrew. After each attack, the salamander resumed unidirectional movement across the leaf litter and, during eight minutes of observation, moved ca. 2 m.

I broke observations briefly to climb down to ground level. When I relocated the salamander two minutes later, she had changed orientation and was moving in the opposite direction. The shrew was not present. I briefly captured and examined the salamander but found no open wounds. She was slightly sticky, presumably from the release of skin secretions, and pieces of organic debris adhered to her body. She was also sloughing portions of the outer epidermal layer. Soon after I released her, the shrew re-appeared and renewed its attack. During the first attack, the shrew grabbed the salamander's tail with its mouth and dragged the writhing salamander backwards through the leaf litter for ca. 30 cm. After ca. ten seconds, the shrew again grabbed the salamander by the tail and pulled her backward through the leaf litter for ca. 50 cm. At 1204 h, the shrew pulled the salamander into an underground cavity and both disappeared from view. Although the fate of the salamander is unknown, I assume she was killed by the shrew.

Analysis of Northern Short-tailed Shrew stomach contents suggest that salamanders constitute a small fraction (1.2%) of the diet (Hamilton 1930. J. Mammal. 11:26–39). However, studies of radio-telemetered salamanders suggest that shrew predation rates may actually be much higher. For example, Madison (1997, *op. cit.*) attributed half of observed Spotted Salamander predation to Northern Short-tailed Shrews, and Madison and Farrand (1998, *op. cit.*) implicated Northern Short-tailed Shrews in the death of one-third of telemetered Tiger Salamanders. My observation indicates that Marbled Salamanders are vulnerable to predation by Southeastern Short-tailed Shrews, a close relative of Northern Short-tailed Shrews (McCay 2001. Mammalian Species 673:1–7). Although laboratory studies show that Marbled Salamanders possess chemical deterrents to attacks by shrews, salamander granular gland secretions become depleted as the number of shrew attacks increase (DiGiovanni and Brodie 1981. Herpetologica 37:234–237). My observation suggests that the shrew used repeated attacks to circumvent the salamander's chemical defenses, rendering it vulnerable to predation.

JOHN G. PALIS, P.O. Box 387, Jonesboro, Illinois 62952, USA; e-mail: jpalis@yahoo.com.

***EURYCEA QUADRIDIGITATA* (Dwarf Salamander). CENTIPEDE PREDATION.** Because of its diminutive size, *Eurycea quadridigitata* is likely vulnerable to a variety of invertebrate and vertebrate predators. However, the only confirmed predators are crayfish (*Procambarus* sp.; Franklin 2000. Herpetol. Rev. 31:98) and Pig Frogs (*Rana grylio*; Lamb 1984. Amer. Midl. Nat. 111:311–318). Herein I report centipede predation of an adult *E. quadridigitata*.

At 1305 h, 11 Dec 2010, I rolled a log in a dry, isolated, cutover *Taxodium ascendens* wetland in Camden Co., Georgia, USA and uncovered an approximately 65-mm long centipede, *Scolopocryptops sexspinosus*, feeding on a Dwarf Salamander (75 mm total length). The centipede had consumed ¾ of the soft tissue on the salamander's head, leaving the skull and mandibles, and had eaten all but the vertebrae from behind the head to approximately mid-body. A single uneaten cirrus indicated the salamander was a male. Upon handling, the salamander's tail slowly undulated, suggesting that capture by the centipede was recent. Inasmuch as these two species have overlapping ranges and select moist microhabitats (Petranka 1998. Salamanders of the United States and Canada. Smithsonian Inst. Press, Washington, D.C. 587 pp.; Shelley 1987. Florida Entomol. 70:498–512), centipede predation of Dwarf Salamanders might occur more often than recognized.

JOHN G. PALIS, P.O. Box 387, Jonesboro, Illinois 62952, USA; e-mail: jpalis@yahoo.com.

***PLETHODON CINEREUS* (Red-backed Salamander). ERYTHRISTIC MORPH.** Throughout its range in northeastern United States and southeastern Canada, *Plethodon cinereus* is a relatively abundant plethodontid inhabiting mixed hardwood-conifer forests. Polymorphism within the species includes the striped

or red-backed color morph, the unstriped or lead-backed color morph, and individuals with characteristics intermediate between the two (Petranka 1998. Salamanders of the United States and Canada. Smithsonian Inst. Press, Washington, D.C. 587 pp.). Leucistic and erythristic individuals have been reported (Mendyk et al. 2010. Herpetol. Rev. 41:189–190; Reed 1908. Amer. Nat. 42:460–465). The erythristic morph, characterized by varying degrees of bright crimson pigmentation on the dorsal, lateral, and ventral surfaces, has been documented among populations in New Brunswick, Nova Scotia, Quebec, Ontario, Massachusetts, Connecticut, New York, and Ohio (Pauley et al. 2001. Northeast. Nat. 8:355–358). In Pennsylvania, the erythristic morph has been reported from Potter and Elk counties within the north central Allegheny High Plateau Province (Hulse et al. 2001. Amphibians and Reptiles of Pennsylvania and the Northeast. Cornell Univ. Press, Ithaca, New York. 419 pp.; Pauley et al. 2001, *op. cit.*).

On 9 Oct 2010 we discovered two adult *P. cinereus* with extensive crimson pigmentation on the dorsal and lateral surfaces of the body, moderate amounts of crimson pigmentation on the ventral surface, and relatively small amounts of dark mottling on the dorsal regions of the head and tail. These salamanders were found under coarse woody debris in a hemlock-northern oak forest ca. 160 m N of Smith Rd. within State Gamelands 69, Crawford Co., Pennsylvania (41.65621°N, 79.90249°W; WGS84). Specimens were measured (26.1, 26.6 mm SVL) and photographed in the laboratory, verified as erythristic morphs by W. E. Meshaka, Jr. (State Museum of Pennsylvania), and deposited in the Clarion University Vertebrate Collections and Museum (CUP A025). We frequently encounter striped red-backed morphs, less frequently encounter erythristic morphs, and have not found unstriped lead-backed morphs at this site. Our report represents the first verification of erythristic *P. cinereus* in Crawford Co. and extends the range of this color morph into the Northwestern Glaciated Province of Pennsylvania.

Several studies provide evidence that erythristic *P. cinereus* are Batesian mimics of the toxic juvenile life stage (red eft) of the Eastern Newt (*Notophthalmus viridescens*) (Tilley et al. 1982. Herpetologica 38:409–417). Throughout the range of *P. cinereus*, the highest population frequencies of the erythristic morph (35.2–47.4%) have been reported from Elk Co., Pennsylvania, where populations are syntopic with those of *N. viridescens* (Cassell and Jones 2005. Northeast. Nat. 12:169–172; Pauley et al. 2001, *op. cit.*). *Plethodon cinereus* and *N. viridescens* are similarly syntopic at our study site. Documenting the microgeographic distribution of both *N. viridescens* and color polymorphism in *P. cinereus* contributes to understanding ecological factors influencing the frequency of each color morph within a population and assessing selective advantages associated with mimicry.

MARC L. McDONALD (e-mail: marcmcd411@gmail.com), **LUCAS J. KIRSCHMAN** (e-mail: l.j.kirschman@gmail.com), and **KURT J. REGESTER** (e-mail: kregester@clarion.edu), Department of Biology, Clarion University, Clarion, Pennsylvania 16214, USA.

***PSEUDOTRITON RUBER* (Red Salamander). LEUCISM.** On 9 June 2009, a leucistic *Pseudotriton ruber* larva was captured in the headwaters of Little Lymans Prong, Macon Co., North Carolina, USA (35.0415°N, 83.5472°W). It was found in relatively deep, liquid mud mixed with detritus in a small seep area connected to a quickly flowing, sandy section of the small stream. Ten additional *P. ruber* larvae were found within the same mud-patch. Most of these larvae exhibited the typical dark brown coloration but some were in the early stages of metamorphosis and had a lighter, more reddish base color. The leucistic individual of unknown sex was entirely white except for darkly pigmented eyes and relatively faint dark mottling along its dorsal side (Fig. 1). The ventral skin was transparent so that some of the visceral organs were visible. The animal was captured alive and transported to the Museum of Comparative Zoology, Harvard University, Cambridge, Massachusetts, where it was kept until it died of unknown causes in late August without showing any signs of approaching metamorphosis. Snout–vent length is strongly correlated with age in *P. ruber* (Bruce and Castanet 2006. J. Herpetol. 40:85–90) and the animal (42 mm SVL) is estimated to have been around 30 months old at the time of its death. Leucism has been reported in a number of plethodontids (Harris 1968. Bull. Maryland Herpetol. Soc. 4:57–60; Mendyk 2010. Herpetol. Rev. 41:189–190; Miller and Braswell 2006. Herpetol. Rev. 37:198; Mitchell and Mazur 1998. Northeast Nat. 5:367–369; Pauley 1974. Redstart 42:104; Rye 1991. Can. Field. Nat. 105:573–574; Seeliger 1945. Copeia 1945:122), but to our knowledge this is the first documented case of leucism in the genus *Pseudotriton*. The specimen has been deposited in the herpetological collection of the Museum of Comparative Zoology, Harvard University (MCZ A-140304).

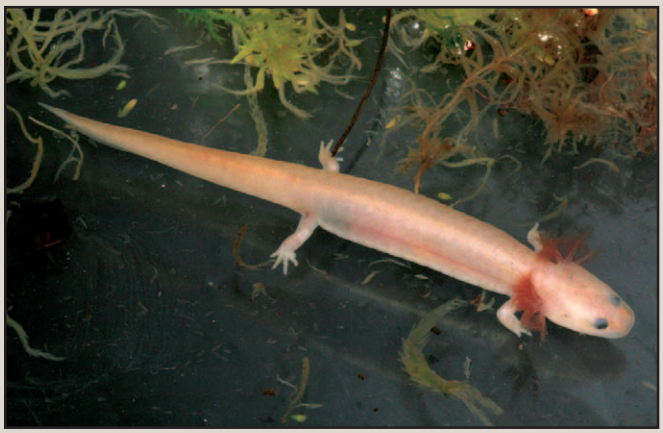

FIG. 1. Leucistic *Pseudotriton ruber* larva from Little Lymans Prong, Macon Co., North Carolina, USA.

COLOR REPRODUCTION SUPPORTED BY THE THOMAS BEAUVAIS FUND

We thank Richard C. Bruce for bringing the locality to our attention and the Volkswagen Foundation, the Highlands Biological Station (Bruce Family Scholarship in Herpetology), and the Museum of Comparative Zoology for funding.

***RHYACOTRITON KEZERI* (Columbia Torrent Salamander). OVIPOSITON SITE.** To date, only eight instances of oviposition attributable to torrent salamanders (genus *Rhyacotriton*) have been described. Nussbaum (1969. Herpetologica 25:277–278) provided the first descriptions, involving *R. kezeri* at two sites in Oregon and Washington. Subsequently, six additional instances of *Rhyacotriton* oviposition have been reported; three more for *R. kezeri* (Russell et al. 2002. Northwest. Nat. 83:19–22), two for *R. variegatus* (Karraker 1999. Herpetol. Rev. 30:160–161; Karraker 2005. Northwest. Nat. 86:24–26), and one for *R. cascadae* (MacCracken 2004. Herpetol. Rev. 35:367). These descriptions reveal

that *Rhyacotriton* deposit large (4–6 mm ovum diameter), unpigmented eggs that are neither attached to the substrate nor to one another. These oviposition sites were concealed in substrates in low-flow headwater habitats (seeps and 1st- and 2nd-order streams). Our purpose here is to describe a sixth *R. kezeri* oviposition site, the first found within a recent clear-cut with no riparian buffer, and to provide the first photograph of a *Rhyacotriton* egg.

We discovered the oviposition site in the course of a landscape study that examined the effects of alternative buffer treatments on stream-associated amphibians in non-fish-bearing streams. The oviposition site was found during surveys of a highly obstructed stream reach (defined as ≥ 70% covered by in-stream woody debris and slash from recent forest harvest activities). Standard methods for surveying stream amphibians could not be effectively applied within these reaches because of the debris. Instead, we cut through or removed woody debris and harvest slash along two narrow lines positioned 3 m apart and perpendicular to the stream axis. Block nets were set flush with the substrate along these lines and all slash in the intervening reach was systematically removed, including excavating into the streambed to a depth of 30 cm or until bedrock was reached. All amphibians found during removal were recorded.

On 26 July 2010 at 1600 h, we discovered a *R. kezeri* oviposition site in one of our headwater study treatment sites. This treatment, a replicate of the most extreme in this study, was a clear-cut harvest with no stream-adjacent forested buffer. Harvest of this 39 to 49-year-old Western Hemlock (*Tsuga heterophylla*) stand had occurred November 2008–January 2009 and was completed 18 months prior to amphibian sampling. No vegetation recovery was evident within the slash-choked footprint along and over the stream channel. Growth of canopy, shrub, and understory vegetation in the adjacent uplands was limited; replanting of young trees had occurred in early 2010. The site was located on a 1st-order reach, 49 m below the upstream origin of the stream, on a quaternary tributary of the North River, Grays Harbor Co., Washington, USA (UTM Zone 10, 46.8121°N, 123.8652°W, WGS84; elev. 157 m). The excavated plot had slash dominated by material 2–10 cm in diameter and to a depth of 1 m. Beneath this slash we encountered 10 eggs buried 15–28 cm beneath a composite substrate of gravel, silt, and small decayed wood pieces. Water seeping through the gravel was 12.5°C (spot measurement with a HBE International Inc. digital thermometer; Collegeville, Pennsylvania; accuracy 1°C); a StowAway TidbiT™ data logger (Onset Computer Corporation, Bourne, Massachusetts; accuracy 0.2°C) 417 m downstream recorded 12.8°C at the same time. Eggs were found singly, unattached, and loosely scattered within this composite substrate over a roughly 30 cm^2 area. Several eggs were also found in the lower block net. The ova were all round and about the same size, but the precise stage of development could not be determined. The one egg measured had a 4-mm cream-white ovum with an 11-mm transparent and a relatively tough jelly capsule. Location of the eggs, carefully re-buried at the site and covered with original slash, was flagged to enable relocation. Two adult females (36 and 41 mm SVL), 2 adult males (42 and 45 mm), 1 adult of unknown sex (35 mm), and 4 larval *R. kezeri* (13, 14, 14, and 26 mm), as well as one neotenic *Dicamptodon* sp. (79 mm) were found in the surveyed stream segment.

We revisited the site twice. We relocated three eggs on 9 Sept 2010 at 1430 h. The ova were slightly elongated and measured 6 mm in long-axis diameter and the capsules measured 14 mm on the long-axis. The tails and heads had become visible and

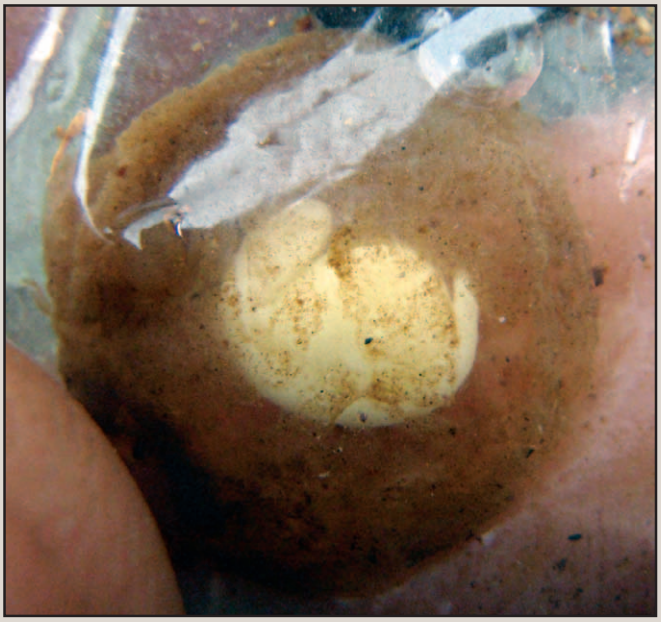

FIG. 1. *Rhyacotrition kezeri* embryo from 9 September 2010 visit. Head of the embryo is on the upper left, the yolk sac is centrally located, and the smaller tail is to the right. Note the fine debris covering the capsule surface.

COLOR REPRODUCTION SUPPORTED BY THE THOMAS BEAUVAIS FUND

embryos showed no visible signs of movement (Fig. 1). One adult *R. kezeri* of unknown sex (not measured) was found within 30 cm of the eggs. Water temperature at the oviposition site was 11.8°C; downstream data logger temperature recorded 11.3°C at the same time. On 4 Oct 2010 at 1150 h, we relocated one empty capsule and one egg containing a live embryo. The yolk sack was elongated, the front arm buds had formed, the tail and head were more developed, the beginning of gills were apparent and the pigmented eyespots were present. Movement of the embryo was observed within the capsule. The empty capsule had a single slit-like opening. No amphibians were observed nearby during this latter visit. Downstream (data logger) water temperature on 4 Oct was 10.2°C.

Two aspects of our observation merit comment. All previous observations of *Rhyacotriton* oviposition sites except for one of *R. variegatus* (Karraker 2005, *op. cit.*) occurred on timber-managed landscapes, but ours is the first to describe oviposition so early in the harvest rotation at a location where no forested buffer was left. This adds to the recent body of data (Kroll et al. 2008. Forest Ecol. Manag. 255:3726–3735; Russell et al. 2004. J. Wildl. Manag. 68:405–417) that suggests that *Rhyacotriton* may not be as sensitive to forestry management practices as previously thought (Corn and Bury 1989. Forest Ecol. Manag. 29:37–57). Second, developmental data for *R. kezeri* are sparse. We observed development from a round egg in which we could not distinguish the developmental stage to a well-differentiated embryo in only 70 days, implying relatively rapid development compared to the only previous report for this species. Nussbaum (1969, *op. cit.*) estimated that development from oviposition to hatching required about 200 days based on the rearing of *R. kezeri* eggs found in the late tail-bud stage in water 8.3°C to hatching in the laboratory at 8.0°C. Our observation might simply reflect higher water temperatures during development; over the interval 26 July–4 October 2010, the downstream data logger recorded temperatures ranging from 9.7–13.3°C.

Fieldwork was supported by the Washington Department of Natural Resources Forests and Fish Adaptive Management Program through the Cooperative, Monitoring, Evaluation, and Research Committee. Weyerhaeuser Co. allowed access to, and facilitated work on, their land. Stephanie Estrella, Bill Ehinger, and Charlotte Wilson (Washington Department of Ecology) provided the temperature data logger data. Studies were done under a programmatic Washington Department of Fish and Wildlife (WDFW) handling permit provided to employees in the course of their work; conditions of this permit require adherence to the guidelines for use of live amphibians and reptiles in the field (Beaupre et al. 2004. Guidelines for Use of Live Amphibians and Reptiles in Field and Laboratory Research, 2nd ed. Herpetological Animal Care and Use Committee of the American Society of Ichthyologists and Herpetologists). J. C. Armstrong, E. M. Lund, and N. E. Gilman (WDFW) assisted with field data collection. Lisa Hallock refined our manuscript. This is contribution No. 28 of the WDFW Habitat Program Amphibian Research Group.

CURTIS E. THOMPSON, JASON M. WALKER, FRITHIOF T. WATERSTRAT (e-mail: Teal.Waterstrat@dfw.wa.gov), **AIMEE P. McINTYRE,** and **MARC P. HAYES,** Washington Department of Fish and Wildlife, Habitat Program, 600 Capitol Way North, Olympia, Washington 98501-1091, USA.

***SIREN INTERMEDIA* (Lesser Siren). LARVAL AND JUVENILE MICROHABITAT.** Adult *Siren intermedia* inhabit a wide range of habitats from temporary and permanent ponds, canals, sloughs, and creeks (Funderburg and Lee 1967. Herpetologica 23:65; Gehlbach and Kennedy 1978. Southwest. Nat. 23:423–430; Neill 1947. Herpetologica 5:19–20; Petranka 1998. Salamanders of the United States and Canada. Smithsonian Inst. Press, Washington, DC. 587 pp.; Smith and Minton 1957. Amer. Midl. Nat. 58:341–351). Microhabitats known for eggs and larvae include leaf-litter depressions in vegetated and muddy pond bottoms (Fauth et al. 1990. Oikos 58:91–99; Noble and Marshall 1932. Amer. Mus. Nov. 532:1–17). We report here another microhabitat feature that apparently influences the distribution of larvae and juveniles in isolated wetlands.

During midday on 16 June 2007, while dipnetting we encountered larval and juvenile *S. intermedia* (four larvae 39–43 mm total length, three juveniles 129–142 mm total length) in a blackwater slough on Cherry Point Marine Corps Air Station, Craven Co., North Carolina, USA. All of the salamanders were closely associated with the extensive fingerlike root masses of *Nyssa biflora* (Swamp Tupelo) in 10–15 cm of water. Eight dipnet sweeps immediately adjacent to these root masses yielded 7 *Siren*. Eleven sweeps in open water >1 m from the root masses yielded no salamanders. The water in this shallow wetland had a suspension of fine, dark organic matter that precluded visibility. Water temperatures at the edge of the root masses (mean = 22.9°C, 21.2–25.0°C, N = 4) were significantly lower than temperatures in the open areas (mean = 26.4°C, 26.1–26.8, N = 4) ($t = -3.913$, $P = 0.008$). Sampling in this slough on 26 July yielded one juvenile *Siren* in the only one of 10 sweeps taken adjacent to the root masses. Larval and juvenile *Siren* may select these root masses to thermoregulate or escape the predatory fish (*Enneacanthus chaetodon, Lepomis macrochirus*) that co-occur in this wetland. Microhabitat structure is apparently a primary factor influencing the distribution and perhaps aggregation of larval and juvenile *S. intermedia* in freshwater wetlands.

ANURA — FROGS

***BUFO BOREAS* (Western Toad). DAVIAN BEHAVIOR.** Misdirected copulation among amphibians has been noted in several species including *Rana boylii* (Bettaso et al. 2008. Herpetol. Rev. 39:462); *R. cascadae* (Garwood and Anderson 2010. Herpetol. Rev. 41:204); *Bufo bufo* (Ayres 2010. Herpetol. Rev. 41:192–193); *B. terrestris,* and *Osteopilus septentrionalis* (Meshaka 1996. Florida Sci. 59:74–75); and *B. marinus* (Lewis 1989. Cane Toads: An Unnatural History. Doubleday, New York. 98 pp.). Those authors alternately referred to Davian behavior as necrogamy. Ayres (2010, *op. cit.*) expanded the use of the term Davian behavior to include misdirected copulations with other species. Here I describe Davian behavior in the Western Toad (*B. boreas*) associated with the federally threatened California Red-legged Frog (*R. draytonii*).

While conducting monitoring surveys in February 2009 for California Red-legged Frogs in eastern Contra Costa Co,,

FIG. 1. Davian behavior by a Western Toad (*Bufo boreas*) attempting to amplex a California Red-legged Frog (*Rana draytonii*).

FIG. 2. Ventral (relative to the California Red-legged Frog, *Rana draytonii*) view of Western Toad (*Bufo boreas*) amplexing a California Red-legged Frog in a manner that has immobilized the frog.

COLOR REPRODUCTIONS SUPPORTED BY THE THOMAS BEAUVAIS FUND

California, USA, I encountered an adult Western Toad in pectoral amplexus with an adult female California Red-legged Frog. Both the toad and frog were on the terrestrial bank of a livestock pond (Fig. 1). The toad was clasped tightly to the frog's thoracic region, while the California Red-legged Frog appeared completely immobilized by the toad.

Davian behavior has been considered an ecological trap because, in this case, the toad was not capable of successfully reproducing (Ayres 2010, *op. cit.*). In this observation, however, neither animal was able to reproduce successfully since both were on land, and reproductively viable conspecifics were in aquatic breeding habitat and not accessible to either individual. Predation events may increase during reproductive activity in many species (Magnhagen 2003. Trends Ecol. Evol. 6:183–186). Here, both individuals were exposed to an increased predation potential due to their distance from water (ca. 1 m). The California Red-legged Frog may have also been subjected to an unanticipated physical stress that was brought on by the Western Toad's grasp (Fig. 2).

On other occasions, I have observed Western Toad males amplexing a root ball of *Juncus balticus*, a piece of cattle dung, and a dead conspecific individual. Arak (*In* Bateson 1983. Mate Choice. Cambridge Univ. Press. New York, New York. 462 pp.) suggested explosive breeding is the reason for necrogamy (Davian behavior). Among the objects reported by Arak (1983, *op. cit.*) were fish and floating debris. I integrate the hypothesis that temporally compressed breeding anurans comprise males that will attempt to amplex appropriately sized nearby objects as a result of breeding pressure from conspecifics. Although Ayres (2010, *op. cit.*) proposed that chemical factors might influence necrogamy in *B. bufo*, I offer that objects of the appropriate size are targets for Davian behavior, and that there is little regard for their composition. I further add that a heterospecific individual attempting to escape amplexus attempts would facilitate complete amplexal behavior by the Western Toad. Although Davian behavior may represent an evolutionary trap for individual Western Toads, it also represents confounding stresses on a threatened species, in this case, the California Red-legged Frog. This observation represents reduced opportunities for reproduction and increased predation risk in both species. Western Toads appear to engage in this behavior at an observable rate, which was observed by me over several years. If the target is a sympatric species, local populations of both the California Red-legged Frog and the Western Toad might be effected.

I thank Sarah M. Foster for her comments and assistance on the manuscript.

***BUFO TERRESTRIS* (Southern Toad). DIET.** *Bufo terrestris* has been reported to prey on a variety of invertebrate species including snails, ants, beetles, crickets, and bees (Dorcas and Gibbons 2008. Frogs and Toads of the Southeast. Univ. Georgia Press, Athens, Georgia. 238 pp.; Jensen et al. [eds.] 2008. Amphibians and Reptiles of Georgia. Univ. Georgia Press, Athens, Georgia. 600 pp.). On 12 July 2007 on Edisto Island, South Carolina, USA, a large adult female *Bufo terrestris* was observed consuming a Marsh Crab (*Sesarma cinereum*). The observation took place in an area where *S. cinereum* are common. This may suggest that *S. cinereum* is available as a significant food source for coastal populations of *Bufo terrestris*.

FIG. 1. *Bufo terrestris* consuming a Marsh Crab (*Sesarma cinereum*), Charleston Co., South Carolina, USA.

HOLLY N. JONES, Riverbanks Zoo and Garden, P.O. Box 1060, Columbia, South Carolina. USA; (e-mail: hjones24@gmail.com.

***CERATOPHRYS CRANWELLI* (Cranwell's Horned Frog). DIET.** Data on the diet of the anurophagous frogs of the Gran Chaco in South America is sparse (Scott and Aquino 2005. *In* Donnelly et al. [eds.], Ecology and Evolution in the Tropics: A Herpetological Perspective, pp. 243–259. Univ. Chicago Press, Chicago, Illinois). One species, *Ceratophrys cranwelli*, is frequently encountered in the Gran Chaco, but only three anurans have been confirmed as comprising part of its diet; *Leptodactylus bufonius* (Schalk 2010. Herpetol. Rev. 41:471), *Physalaemus biligonigerus*, and an unidentified *Leptodactylus* sp. (Scott and Aquino 2005, *op. cit.*).

On 31 Dec 2010 at 2230 h we came upon a pair of *C. cranwelli* in amplexus in a temporary pond (19.60434°S, 62.57558°W; WGS 84) in the Isoceño community of Yapiroa, Province Cordillera, Department of Santa Cruz, Bolivia. While being grasped by the male *C. cranwelli*, the female was observed eating an adult *Physalaemus albonotatus* (Fig. 1). The *P. albonotatus* made continuous attempts to free itself from the mouth of the female, but it was consumed after approximately ten minutes. The pair remained on the edge of the pond for two minutes, after which the female (with the male still grasping her) then lunged at a male

FIG. 1. A female *Ceratophrys cranwelli* consuming a *Physalaemus albonotatus* while being amplexed by a male *C. cranwelli*. Located in the lower right of the photo is the male *Rhinella major* that the female *C. cranwelli* attempted to capture after ingesting the *Physalaemus*.

Rhinella major that was calling approximately 10 cm away (visible in Fig. 1). The female *C. cranwelli* failed to capture the *R. major*, which escaped into a nearby cluster of plants. The pair then swam into the middle of the pond, presumably to mate. This observation confirms one additional anuran species and supports the possibility of another anuran species in the diet of *C. cranwelli*.

Funding was provided by the National Science Foundation's Graduate Research Fellowship Program (awarded to CMS).

***CHAPERINA FUSCA* (Saffron-bellied Frog). OCULAR ANOMALY.** *Chaperina fusca* is a small anuran (to 26 mm SVL) with an oval-shaped body, small head, blunt and projecting snout, fine dermal spine on each elbow and heel, greenish or bluish black dorsum with whitish or bluish dots, brown limbs with dark bars, and the highly distinctive ventral coloration of numerous yellow to rich yellow blotches bordered by a dark brown network (Inger 2005. The Systematics and Zoogeography of the Amphibia of Borneo. Natural History Publications [Borneo] Sdn. Bhd. Kota Kinabalu. 402 pp.; Inger and Stuebing 2005. A Field Guide to the Frogs of Borneo. Second ed. Natural History Publications [Borneo] Sdn. Bhd. Kota Kinabalu. 201 pp.). *Chaperina fusca* dwells in primary or old secondary forests on the forest floor and sometimes in low vegetation from near sea level to 1800 m elev., and the adults move to water bodies, especially those with decaying plant materials, to breed (Inger 2007. Systematics and Zoogeography of Philippine Amphibia. Natural History Publications [Borneo] Sdn. Bhd. Kota Kinabalu. 370 pp.; Malkmus et al. 2002. Amphibians and Reptiles of Mount Kinabalu [North Borneo]. A.R.G. Gantner Verlag K.G. Ruggell. 424 pp.). The species occurs in Central Peninsular Thailand, Peninsular Malaysia, Borneo (Sabah and Sarawak of Malaysia, Brunei Darussalam, and Kalimantan of Indonesia), and southern Philippines (Palawan, Mindanao, and Sulu Archipelago) (Das 2007. A Pocket Guide: Amphibians and Reptiles of Brunei. Natural History Publications [Borneo] Sdn. Bhd. Kota Kinabalu. 200 pp.; Frost 2010. Amphibian Species of the World: an Online Reference. Version 5.3 [8 April 2010]. Electronic database accessible at http://research.amnh.org/vz/herpetology/amphibia/. American Museum of Natural History, New York. Accessed on 22 Dec 2010).

On 5 Dec 2010 at 1910 h, an adult *C. fusca* (21 mm SVL, 1.1 g) was collected at an artificial pond within the compound of Haleluyah Retreat Centre (6°N, 116.536°E; 1518 m elev.), Bundu Tuhan, Ranau District, West Coast Division, Sabah, Bornean Malaysia. Air temperature was 18.7°C, and relative humidity was 84.1%. The anuran was missing a right eye, while the left eye was normal (Fig. 1). Anuran deformities can be attributed to physical injuries, infections and diseases, exposure to chemicals, UV radiation, mutation, and developmental errors (Adams et al. 2008. Herpetol. Rev. 39:460–461; Silva and Toledo 2010. Herpetol. Rev. 41:333–334; Streicher et al. 2010. Herpetol. Rev. 41:208–209). Close examination showed no body injuries. The pond and surrounding vegetation are not adjacent to any source of chemical pollutants and effluents. pH of the pond water was 7.48. On the same night, another *C. fusca* (25 mm SVL, 1.5 g) was collected at the same pond but without ocular anomaly or other deformities. By comparison, the *C. fusca* with ocular anomaly exhibited lighter dorsal and ventral hues. Otherwise, the anuran seemed unaffected by the anomaly as it was agile during an indoor *ex-situ* photography session. The specimen (HEP01794) was deposited in BORNEENSIS, the Bornean reference collection of the Institute for Tropical Biology and Conservation, Universiti Malaysia Sabah. To our knowledge, this is the first observation of ocular anomaly in *C. fusca*.

FIG. 1. Left: Front view of an adult *Chaperina fusca* with ocular anomaly found in the Haleluyah Retreat Centre compound, Ranau, Sabah, Malaysia. Right: Dorsolateral view.

We are grateful to Haleluyah Retreat Centre for permission to collect specimens and to the Institute for Tropical Biology and Conservation, Universiti Malaysia Sabah for support.

***CYCLORANA AUSTRALIS* (Giant Frog). EMERGENCE.** Amphibians in seasonally dry or desert environments become active when water is available. During prolonged dry periods many frogs burrow to avoid desiccating conditions. Rainfall is required to facilitate emergence from burrows and induce aboveground activity (Cartledge et al. 2006. J. Exp. Biol. 209:3309–3321; Mayhew 1965. Amer. Midl. Nat. 74:95–109; Morton et al. 1993. The Beagle 10:67–70; Poynton and Pritchard 1976. Zool. Africana 11:313–318), including foraging and spawning (Balinsky 1969. Zool. Africana 4:37–93; Wells 2007. The Ecology and Behavior of Amphibians. Univ. Chicago Press, Chicago, Illinois. 1148 pp.).

Cyclorana australis is a fossorial species from northern Australia that forms a cocoon (Christian and Parry 1997. Aust. J. Zool. 45:13–20; Withers 1998. Aust. J. Zool. 46:405–418). Monsoonal northern Australia has markedly seasonal rainfall with the great majority falling in the summer rainy season. Each year during the prolonged dry season, *C. australis* spend approximately six months underground in shallow burrows (<15 cm deep; Tracy et al. 2007. Copeia 2007:901–912). From previous studies, it is known that the frogs usually bury in April and May as rainfall attenuates. The frogs emerge following intermittent rains during the pre-monsoonal period (usually October–November), but there are no data concerning the amount of rainfall required for mass emergence of frogs in this environment.

To determine the amount of rainfall required to induce emergence from underground burrows, field investigations were carried out during the onset of the wet season in 2007. The Mickett Creek area (12.4108°S, 130.9436°E) near Darwin, Northern Territory, was visited regularly at night and searched on foot with the aid of a spotlight. A transect through the area was followed and known breeding chorus aggregation sites were visited. The total number of *C. australis* observed by sight was noted (some individuals were located by call). Sex was determined as male if

TABLE 1. Emergence of *Cyclorana australis* and cumulative rainfall near Darwin, Northern Territory, Australia during onset of the 2007 wet season.

Date	Cumulative rainfall (mm)	Frogs observed	Male	Female
23 Oct.	0.5	0	0	0
1 Nov.	2.5	0	0	0
6 Nov.	49	3	3	0
12 Nov.	83	5	4	1
13 Nov.	114	32	24	8

the individual was calling, and if not calling the frog was captured and inspected for the presence of nuptial pads and dark throat coloration that develops in the males during the breeding season. The distance of calling males to the edge of the nearest standing water was estimated to the nearest cm. During each visit, rainfall data were obtained from a gauge at the site. Rainfall is reported as cumulative from the start of October.

Although *Crinia remota, Litoria nasuta, L. tornieri, L. microbelos, L. rubella,* and *L. bicolor* were observed at night in the dry season, *C. australis* was not observed at the site before November (and had not been observed since March). Emergence of some *C. australis* occurred with 49 mm of cumulative rainfall (ca. 47 mm fell over a period of three days), but near 100 mm was required before large breeding choruses formed on 13 Nov (Table 1). More than 10 specimens of the congeneric but smaller cocooning species *C. longipes* were also observed on that date. The sex ratio of observed *C. australis* was approximately 3:1 M/F, and included three amplectant pairs on 13 Nov. There is probably some bias in the sex ratio data due to the tendency of males to vocalize, thereby increasing the likelihood of detection. Males were invariably calling from positions on moist ground near puddles and small pools; mean distance to the water's edge was 2.18 ± 2.15 m SD (N = 19). All but two calling individuals were less than 3 m from water.

Rainfall intensity, the temporal spacing of rainfall events, topography, and substrate permeability are the main factors that determine water infiltration depth. Approximately 50 mm of rainfall was required to moisten the soil, allowing *C. australis* to emerge, and large choruses developed with further rainfall. Although some individuals emerged early, the overall pattern was of mass emergence with close synchrony in timing. Rainfall is an important trigger for emergence because dry savanna soils are impenetrable in the late dry season, and *C. australis* are likely entombed in the burrow chamber until the soil is moistened. *Cyclorana australis* is one of the first anurans to breed in the Darwin region, and it is probable that shallow burrows facilitate early emergence. In 2010 *C. australis* emerged in mid October following early rains, whereas in 2006 they were not observed until early December, suggesting that there is substantial interannual variation in emergence time.

STEPHEN J. REYNOLDS, School of Environmental and Life Sciences, Charles Darwin University, Darwin NT 0909, Australia; e-mail: steve.reynolds@cdu.edu.au.

***INCILIUS CONIFERUS* (Green Climbing Toad). BREEDING BEHAVIOR.** *Incilius coniferus* is a moderate sized (53–94 mm SVL), semi-arboreal bufonid native to the Atlantic lowlands of southern Nicaragua and the Pacific lowlands of southwestern Costa Rica to northwestern Ecuador. It is known to breed in the dry season, which occurs from December to April in Costa Rica (Guyer and Donnelly 2005. Amphibians and Reptiles of La Selva. Univ. California Press, Berkeley. 367 pp.; Savage 2002. The Amphibians and Reptiles of Costa Rica: A Herpetofauna Between Two Continents, Between Two Seas. Univ. Chicago Press, Chicago, Illinois. xx + 934 pp.). Courtship typically occurs after rains in shallow pools in forests, as well as relatively open areas (Guyer and Donnelly 2005, *op. cit.*; Savage 2002, *op. cit.*). Crump (1989. Oecologia 78:486–489) reported that *I. coniferus* oviposits in May at the beginning of the wet season in Costa Rica. Porter (1966. Herpetologica 22:60–67) observed a calling male on 10 July in Costa Rica, but did not mention if mating occurred. Detailed reports of reproductive activity from Panama are lacking, but the timing is most likely similar. Here I report a pulse of breeding activity in Panama, outside of the expected breeding season for this species.

At 1800 h on 13 Sept 2010, I observed five male and one female *I. coniferus* in water-filled ruts formed by tires on a dirt road following the continental divide just inside the southern border of Parque Nacional Division General Omar Tarrijos Herrera, Panama (8.400859°N, 80.35345°W, WGS 84; elev. ~770 m). In the area where the wheel ruts collect water, the road widens from ca. 3 m to 13 m and is bordered by moderate to tall grass cover. The habitat is consistent with the description given by Crump (1989, *op. cit.*). Four of the five males were calling, while the remaining male was in axial amplexus with the female. At 0745 h the following morning, four pairs of toads in amplexus were depositing eggs, or had just done so (Fig 1). At 1645 h on that second day, no toads were present, except for two female specimens, both dead with their arms and legs removed, observed in two separate tire ruts. Although this could represent predation, it is also possible that the toads were killed by humans who believe negative superstitions about toads (J. Ray, pers. comm.). The following night at 2020 h, no *I. coniferus* were observed, but the eggs were still present. I surveyed areas within the park on three separate occasions for a total of eight days (17–19 Aug, 13–15 Sept, and 29–30 Oct) and did not encounter any additional *I. coniferus* other than the individuals reported here.

The wet season in Panama includes a reduction of rainfall in July, which averages 243 mm of rain, whereas June and Sept receive 300.8 and 342.4 mm of precipitation, respectively. Still, July receives more rainfall on average than the dry season (e.g., 94.7 mm in April; World Meteorological Organization 2010. http://www.wmo.int). Crump (1989, *op. cit.*) reported that *I. coniferus*

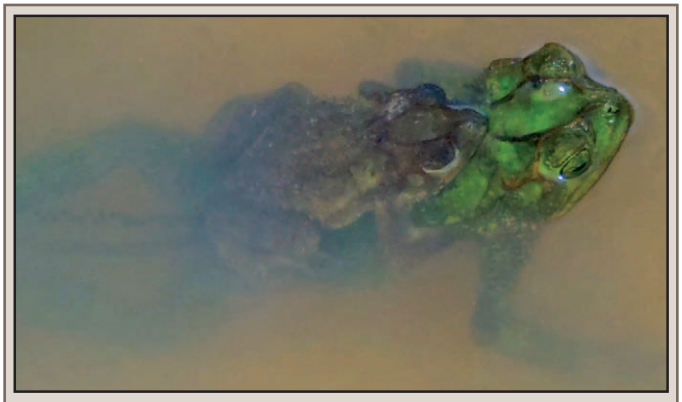

FIG. 1. A pair of *Incilius coniferus* in amplexus, with female depositing eggs, in Parque Nacional Division General Omar Tarrijos Herrera, Panama.

breeds in May, a time when precipitation is increasing. The climate in May is similar to Sept in that both months experience a marked increase in precipitation compared to the preceding months (mean monthly precipitation of 96.7 mm in April increases to 313.7 mm in May, and 243 mm in July increases to 342.4 mm in Sept). This climate pattern is similar to what is experienced in Costa Rica. It is possible that breeding is triggered by the increase precipitation at the end of the rainy season, and as a result the end of the mini dry season may trigger a similar breeding event. On first day of the observation (13 Sept) it rained from ~1300 h to ~1700 h, which is typical weather of the area in Sept. Considering the range of reported breeding activity, the reproductive cycle of *I. coniferus* warrants more investigation, particularly in Panama.

I thank J. Knight, K. Knight, S. Mullin, and the EIU Herpetology Lab, and especially J. Ray and the staff at La MICA Biological Station for their assistance.

KYLE A. BAUMGARTNER, Department of Biological Sciences, Eastern Illinois University, Charleston, Illinois 61920, USA; e-mail: kabaumgartner@eiu.edu.

FIG. 1. An adult *Osteocephalus taurinus* being preyed upon by an adult *Leptodeira annulata* in a gallery forest at Lucas do Rio Verde, state of Mato Grosso, Brazil.

***OSTEOCEPHALUS TAURINUS* (Manaus Slender-legged Treefrog). PREDATION.** Amphibians are common prey for a great variety of vertebrates, arthropods, and even carnivorous plants (Duellman and Trueb 1986. Biology of Amphibians. McGraw-Hill, New York; Pough et al. 1998. Herpetology. Prentice-Hall, New Jersey). Snakes are among the most representative vertebrate predators of anurans (Toledo et al. 2007. J. Zool. 271:170–177).

Male *Osteocephalus taurinus* may reach 71–92 mm, while females reach 90–101 mm (Lima et al. 2006. Guia de Sapos da Reserva Adolpho Ducke, Amazônia Central. Áttema, Manaus). The species occurs in the Amazon Basin of Ecuador, Brazil, Bolivia, Peru, Colombia, as well as in the upper Orinoco Basin of Venezuela, and Guiana (Frost 2010. Amphibian Species of the World: an Online Reference. Ver. 5.5 [31 January 2011]. Electronic database accessible at http://research.amnh.org/vz/herpetology/amphibia/. American Museum of Natural History, New York). It occurs in forested habitats throughout the Amazon Forest, and in gallery forests within the open Cerrado biome, in Mato Grosso and Maranhão, Brazil (IUCN 2010. Conservation International and NatureServe. Global Amphibians Assessment. http://www.globalamphibians.org. Accessed 22 Aug 2010). We here report predation of *O. taurinus* by *Leptodeira annulata*.

On 08 Jul 2010 at 1911 h, near the margin of a stream in gallery forest in the municipality of Lucas do Rio Verde, state of Mato Grosso, Brazil, a distress call in the leaf litter revealed an adult *O. taurinus* being predated by an adult *L. annulata* (Fig. 1). The snake seized the treefrog by the inguinal region, but freed it still alive, upon capture. After been placed in a plastic bag with its prey, the snake proceeded to swallow it. Both specimens were collected and deposited at the Coleção Zoológica de Vertebrados of the Universidade Federal de Mato Grosso (municipality of Cuiabá, Mato Grosso State, Brazil), accession number UFMT 8770.

Anurans are common prey of *L. annulata* (Cantor and Pizzatto 2008. Herpetol. Rev. 39:462–463; Martins and Oliveira 1999. Herpetol. Nat. Hist. 6:78–150; Morais and Ávila 2006. Herpetol. Rev. 37:76; Vitt 1996. Herpetol. Nat. Hist. 4:69–76). To our knowledge, this is the first report of *L. annulata* preying upon *O. taurinus*, one of the most abundant anurans among gallery forests at Lucas do Rio Verde. Much of the original vegetation in this municipality has been removed for the establishment of huge plantations of soybeans and other grains, and only narrow strips of gallery forest are left among the matrix of cultivated land. We here emphasize the importance of promoting effective measures for the conservation of these forested relicts, which offer conditions for the successful establishment of populations of anurans such as *O. taurinus*, and their predators, including *L. annulata*.

We thank Fabrício H. Oda for comments on this manuscript.

***PLATYMANTIS SPELAEUS* (Cave Wrinkled Ground Frog). DIRECT DEVELOPMENT.** *Platymantis spelaeus* is endemic to southern Negros Island, Philippines, and is one of four recognized species of Philippine limestone forest frogs. All species of the genus *Platymantis* are recognized as direct developing frogs, often laying egg clusters on aerial leaves, branches, or ground leaf litter (Brown and Alcala 1982. Proc. Biol. Soc. Washington 95:386–391; Brown and Alcala 1983. *In* Rhodin and Miyata [eds.], Advances in Herpetology and Evolutionary Biology: Essays in Honor of Ernest E. Williams, pp. 416–428. Museum of Comparative Zoology, Harvard University, Cambridge, Massachusetts). It has been hypothesized that all four obligate karst forest species breed in limestone crevices and small caves (Brown and Alcala 2000. Haring Ibon 2:19–22; Brown et al. 2003. Haring Ibon 43:91–109; Siler et al. 2007. Herpetologica 63:351–364; Siler et al. 2009. Herpetologica 65:92–104); however, to date, no data have been presented in direct support of this hypothesis. To our knowledge, this is the first evidence of direct development in cave systems for species of the genus *Platymantis*.

While conducting fieldwork in the Philippines, we observed newly metamorphosed juvenile *Platymantis spelaeus* inside a

COLOR REPRODUCTIONS SUPPORTED BY THE THOMAS BEAUVAIS FUND

FIG. 1. An adult male (top) and a newly metamorphosed juvenile (bottom) *Platymantis spelaeus* in southwest Negros Island, Philippines.

small cave system, 2–4 m from the entrance to the cave. The observation was made on 27 Oct 2004, in secondary-growth forest, in the Municipality of Cauayan, Barangay Camalandaan, Negros Occidental Province, Negros Island, Philippines (9.8378667°N, 122.5053667°E, WGS 84; elev. 350 m). Adult specimens were observed calling on karst formations surrounding the cave system. One adult (CDS 266, male, 49.0 mm SVL, 8.9 g, Fig. 1a) and three juvenile (PNM Developmental Series 07; juvenile 1, 8.26 mm SVL, Fig. 1b; juvenile 2; 8.38 mm SVL; juvenile 3, 8.14 mm SVL) specimens were deposited in the herpetological collections of the Philippine National Museum.

CAMERON D. SILER, Department of Ecology and Evolutionary Biology, Natural History Museum and Biodiversity Institute, University of Kansas, Dyche Hall, 1345 Jayhawk Blvd, Lawrence, Kansas 66045-7561, USA (e-mail: camsiler@ku.edu); **LEONARDO AVERIA**, Silliman University, Angelo King Center for Research and Environmental Management, Dumaguete City, Negros Island, Philippines (e-mail: suakcrem@yahoo.com).

***PLEURODEMA CORDOBAE* (Octoploid Pleurodema). CLUTCH SIZE.** *Pleurodema cordobae* is only known from the type locality and little is known about the reproductive biology and natural history of this recently described species. The species is known to lay eggs in semi-submerged gelatinous egg masses that adhere to vegetation (Valetti et al. 2009. Zootaxa 2073:1–21). Herein we document the number of eggs per egg mass and the density of egg masses in two ponds at the type locality.

On 2 Dec 2010 we visited two ponds at Estancia Los Tabaquillos, Córdoba province, Argentina (32.3995°S, 64.926°W, ca. 2105 m elev.) and observed numerous egg masses of *P. cordobae*. The embryos in different egg masses were staged at Gosner 15 and 19 (Gosner 1960. Herpetologica 16:183–190). The area of the larger pond was 236 m^2; clutch number was 203, and density of egg masses was 0.86/m^2. In the smaller pond (7 m^2), clutch number was 27 and density of egg-masses was 3.82/m^2. The average number of eggs per egg mass was 137 (N = 11; range = 74–215; SD = 45.9).

The eggs masses were adhered to vegetation which was most abundant along the edge of the ponds, thus the greatest density of nests in the smaller pond could be due to the higher edge/area rate.

***PSEUDOEPIDALEA BRONGERSMAI* (Brongersma's Toad). PREDATION.** Among arthropods, spiders are well known as predators of reptiles and amphibians (Armas 2000. Revista Ibérica de Aracnologia 3:87–88; Manzanilla et al. 2008. Bol. Soc. Entomológica Aragonesa 42:317–319; Barbo et al. 2009. Herpetol. Notes 2:99–100; Maffei et al. 2010. Herpetol. Notes 3:167–170).

FIG. 1. Dry metamorph of *Pseudoepidalea brongersmai*, partially eaten on the head and right foreleg (arrow).

FIG. 2. *Arctosa* sp. (Family: Lycosidae).

Most of the reports are from tropical areas where large species of spiders occur (Barej et al. 2009. Herpetol. Notes 2:137–139; Maffei et al. 2010, *op. cit.*), while similar observations in desert areas are lacking, although large species of spiders occur there.

Pseudoepidalea brongersmai (Frost et al. 2006. Bull. Am. Mus. Nat. Hist. 297:1–370) is the least known member of the family Bufonidae occurring in southwestern Morocco (García-Muñoz et al. 2009. Herpetol. Notes 2:231–233). Only a few reports on its biology have been published (Bogaerts 2001. Podarcis 2[3]:81–88; Gallix 2002. Unpubl. MS thesis EPHE. Mémoire, Ecole Pratique des Hautes Etudes, Montpellier; García-Muñoz et al. 2009, *op. cit.*; Grillitsch et al. 1989. Amphibia-Reptilia 10:215–229; Herrero et al. 1993. J. Herpetol. 27[4]:463–465; Hoogmoed 1972. Zool. Mededelingen 47[5]:49–64), and none of them provides information on predators. Here, we report the first case of predation by a spider on a juvenile *P. brongersmai*.

A dry stream north of Marrakech (Skour-rehamna, 32.493030°N, 7.908570°W) was searched for amphibians on 2 May 2010. Numerous recently metamorphosed *P. brongersmai* were detected under rocks and plastic debris, and 17 were collected and photographed against a grid paper (18.4 ± 3.6 mm SVL). In addition, one dry metamorph with signs of having been partially eaten by a spider (Fig. 1) was found in a spider (Lycosidae, *Arctosa* sp.; Fig. 2) burrow. Although we did not see the spider eating the toad, the association of the dead toad to other dry insect remnants typical of spider feeding, together with the wounds on the body, suggests predation. To our knowledge this is the first report of predation of *P. brongersmai* by a spider, providing new information on the predators and on the juvenile stage of this species.

Field work was supported by the projects PTDC/BIA-DE/67678/2006 and PTDC/BIA-BEC/101256/2008, funded by "Fundação para a Ciência e a Tecnologia, FCT" (Portugal), and conducted under permit N 14 HECEFLCD/DLCDPN/CFF of the "Haut Commissariat aux Eaux et Forêts et à la Lutte Contre la Désertification" (Morocco). EGM was supported by post-doc funding from FCT (SFRH/BPD/72806/2010). The authors thank P. Sousa for spider identification.

***PSEUDOPALUDICOLA* CF. *MYSTACALIS*. PREDATION.** Amphibians are consumed as prey by a large number of vertebrates and invertebrates at some stage of their life (Duellman and Trueb 1986. Biology of Amphibians. McGraw Hill, New York. 670 pp.). Although spiders are ingested by a large number of frogs, spiders predating on frogs have been reported by several authors playing an important role especially during the reproductive period or during metamorphosis (Pombal Jr. 2007. Rev. Bras. Zool. 24:841–843). However, in Brazil, predation by spiders is only reported from the Amazon (Menin et al. 2005. Phyllomedusa 4:39–47), the Mata Atlântica (Toledo 2005. Herpetol. Rev. 36:395–400), and the Cerrado (Maffei et al. 2010. Herpetol. Notes 3:167–170), but not from the Caatinga biome.

FIG. 1. *Lycosa* cf. *erythrognata* predating on *Pseudopaludicola* cf. *mystacalis*.

Our observations were conducted next to a permanent pond in an area of Caatinga situated in the municipality of Riacho de Santana (13.929397°S, 43.109864°W), state of Bahia, northeastern Brazil. At the margins of the pool, we detected numerous species of anurans including *Pseudopaludicola* cf. *mystacalis*. On 19 Oct 2009 at ca. 2100 h, we observed the spider *Lycosa* cf. *erythrognata* preying on an individual *P.* cf. *mystacalis* (Fig. 1). The spider attacked the frog at the edge of a puddle and held the frog for about three minutes, then pulled its chelicerae slowly out with the help of pedipalps. Once they were removed the frog was already dead. During our survey, we often found these spiders foraging at the study site. This observation suggests that spiders may be important predators of small frogs in the Caatinga.

We thank D. Rödder for reviewing the manuscript.

RICARDO LOURENÇO DE MORAES, Programa de Pós-Graduação em Ecologia e Conservação da Biodiversidade, Universidade Estadual de Santa Cruz (UESC), Rodovia Ilhéus-Itabuna, km 16, Ilhéus, Bahia, Brazil, CEP 45662-000 (e-mail: ricardo_lmoraes@hotmail.com); **WESLEI PERTEL,** Programa de Pós-Graduação em Zoologia, Universidade Estadual de Santa Cruz (UESC), Rodovia Ilhéus-Itabuna, km 16, Ilhéus, Bahia, Brazil, CEP 45662-000 (e-mail: wpertel@yahoo.com.br).

***RANA DRAYTONII* (California Red-Legged Frog). PREDATION.** Important causes for the decline of *Rana draytonii* are thought to be habitat loss, exploitation by the restaurant industry (Jennings and Hayes 1985. Herpetologica 41:94–103), and competition and predation from introduced fishes and frogs (Moyle 1973. Copeia 1973:8–22). By the time the California Red-legged Frog was federally listed in 2002, it had disappeared from much of its original range, leaving little opportunity to study interactions between this native species and the introduced American Bullfrog (*Rana catesbeiana*). Competition between the two species at the larval life stage has been described (Lawler et al. 1999. Cons. Biol. 13[3]:613–622), and two recent reports have established that adult American Bullfrogs prey upon the tadpole and juvenile stages of *R. draytonii* (Cook and Jennings 2001. Herpetol. Rev. 323:182–183) and on adults (Cook 2002. Herpetol. Rev. 33:303). The following account of a recent instance of opportunistic predation by American Bullfrogs illuminates their threat potential to the recovery of California Red-legged Frog populations.

On 3 Sept 2010, I discovered 23 recently metamorphosed *R. draytonii* distributed around the perimeter of an unnamed stock pond in Sonoma Co., California, USA (38.3301°N, 122.5818°W). This small pond (~270 m^2) was constructed approximately 20

years ago in heavily grazed rangeland, and this account marks the first sighting of California Red-legged Frogs at this location. The pond and its surroundings are devoid of vegetation; the newly transformed frogs were basking in shallow water or sought cover in refugia created by deep cow tracks at the pond edge. I also observed, collected, and dispatched seven adult American Bullfrogs present at the pond and analyzed their stomach contents. Among the seven American Bullfrogs (five gravid females and two males), each of four females (SVL 136–144 mm) had one newly transformed juvenile (SVL 26–31 mm) California Red-legged Frog in their stomach, and two of them had two each. Each of the seven American Bullfrog stomachs also contained at least one California Newt (*Taricha torosa*) larva (≤ 3) and aquatic insects (notonectids, ≤ 13).

Predator-prey interactions are seldom witnessed in the wild due to their short duration and disturbance by observer presence (Major 1990. Ibis 132:608–612), but predation events may be inferred from the stomach contents of predators. The above incident, and those described by Cook and Jennings (2001, *op. cit.*) and Cook (2002, *op. cit.*), suggest that predation by American Bullfrogs on California Red-legged Frogs might be more widespread than previously observed. Both species occupy the same ponds with some regularity (Cook and Jennings 2007. Herpetologica 63[4]:430–440). Considerable overlap occurs in the preferred diet of adult American bullfrogs and California Red-legged Frogs (Hayes and Tenant 1985. Southwest. Nat. 30[4]:601–605), and continued loss of habitat concentrates resources, bringing these two species together with greater frequency.

In a controlled experiment (Corse and Metter 1980. J. Herpetol. 14[3]:231–238) adult American Bullfrogs that were forcefed a diet of juvenile conspecifics completely digested their meal in 41 h. At the Sonoma Co. stock pond described above, two of the American Bullfrogs had each eaten two juvenile California Red-legged Frogs. If each adult American Bullfrog ate two California Red-legged Frogs, given the observed rate of digestion described above, the seven adult American Bullfrogs present could potentially consume all 23 of the observed juvenile California Red-legged Frogs over a four-day period. Adult California Red-legged Frogs probably prey on juvenile American Bullfrogs, but the coexistence of these two frog species at ponds may belie a dynamic predator-prey relationship that favors the larger American Bullfrogs. The presence of American Bullfrogs in historical California Red-legged Frog habitat could pose a serious threat to the recovery of this threatened species.

American Bullfrogs were collected under a California fishing license (059753-12). I thank D. G. Cook for his continued support.

JEFFERY T. WILCOX, University of California, Berkeley, Blue Oak Ranch Reserve, 23100 Alum Rock Falls Rd., San Jose, California 95127, USA; jtwilcox@berkeley.edu.

***SCINAX NASICUS* (Lesser Snouted Treefrog) and *SCINAX ACUMINATUS* (Mato Grosso Snouted Treefrog). REFUGIA.** *Scinax nasicus* occurs in Paraguay, northern and central Argentina (south to Córdoba and Buenos Aires provinces), Uruguay, eastern Bolivia, and southern Brazil. *Scinax acuminatus* occurs in southern Mato Grosso and Mato Grosso do Sul (Brazil), Paraguay, Bolivia (Santa Cruz), and northern Argentina (Frost 2011. Amphibian Species of the World: an Online Reference. Version 5.5, 31 Jan 2011. Electronic database accessible at http://research.amnh.org/vz/herpetology/amphibia/, American Museum of Natural History, New York). From Sept–Dec 2009, we conducted surveys ca. 10 km NE Corrientes City, Argentina (27.4321°S, 58.7466°W). The study site is part of the Chacoan Domain, Oriental Chaco District (Cabrera and Willink 1980. Biogeografía de América Latina. Secretaría Federal OEA. Monografía 13:1–122; Carnevali 1994. Fitogeografía de la Provincia de Corrientes. Gobierno de la provincia de Corrientes e INTA, 324 pp.), and is characterized by the presence of numerous temporary, semi-permanent, and permanent water bodies. Mean annual precipitation is 1500 mm and mean annual temperature is 23°C. According to Carnevali (1994, *op. cit.*), the original plant formation at this site was *Schinopsis balansae* "quebracho" forest, which is currently extremely degraded and largely replaced by sclerophyllous forest with a prevalence of *Prosopis affinis, P. nigra, Acacia caven, Celtis* sp., and numerous colonies of *Aechmea distichantha* and *Bromelia* sp.

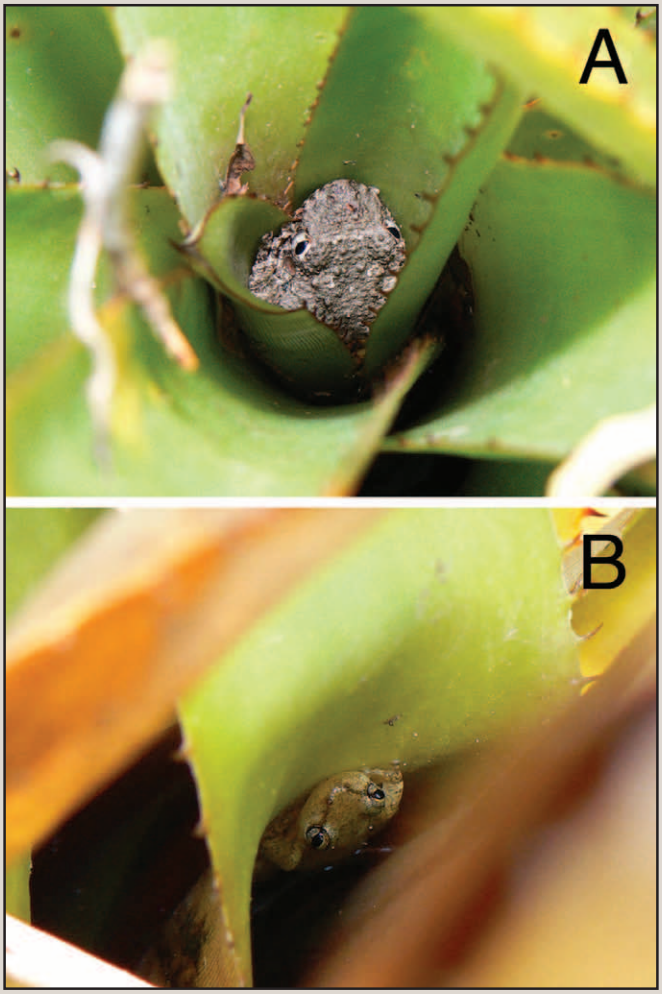

FIG. 1. A) *Scinax acuminatus* and B) *Scinax nasicus* hidden inside the axils of *Aechmea distichantha.*

COLOR REPRODUCTIONS SUPPORTED BY THE THOMAS BEAUVAIS FUND

Numerous amphibian species are associated with bromeliads, using them strictly as shelter or for entire life cycle, reproducing and feeding inside the plant axil (Peixoto 1995. Rev. Univ. Rural, Sér. Ciênc. da Vida 17[2]:75–83). In the study area, the bromeliad *Aechmea distichantha* mainly is used as a refuge for various species of amphibians and reptiles. This species has a high structural complexity and the capacity to store water for long periods (phytotelmata), such that individual plants harbor a diversity of arthropods and thus provide shelter and food for amphibians.

In the study period we found *Scinax nasicus* (N = 60) and *S. acuminatus* (N = 5) using *A. distichantha* as refugia (Figs. 1A, B).

Often, we recorded more than one frog per plant. In some cases, we found up to five specimens of *S. nasicus* (juveniles) inhabiting the same plant, each positioned in different leaf axils. *S. acuminatus*, however, was found with much less frequency. The observations were made between 9000 to 1800 h and in all cases, the frogs were hidden, with no evidence of activity such as eating or vocalization. Unfortunately, in September 2010, the study area habitat was completely lost due to land conversion by property owners.

MARTA I. DURÉ (e-mail: martadure@yahoo.com) and **EDUARDO F. SCHAEFER** (e-mail: eclschaefer247@yahoo.com.ar), Centro de Ecología Aplicada del Litoral CECOAL-CONICET, Ruta 5, Km 2,5. C.P. 3400, Corrientes, Argentina.

TESTUDINES — TURTLES

***CHELONIA MYDAS AGASSIZII* (East Pacific Green Seaturtle) DIET.** The East Pacific Green Turtle is considered the most carnivorous of all Green Seaturtle subpopulations worldwide (Bjorndal 1997. *In* Lutz and Musick [eds.], The Biology of Sea Turtles, pp. 199–231. CRC Press, Boca Raton, Florida). Novel Green Turtle diet items have been reported, including the Sea Pen, *Ptilosarcus undulatus* (Seminoff et al. 2002. Copeia 2002:266–268), pelagic red crabs, *Pleuroncodes planipes* (Lopez-Mendilaharsu et al. 2005. Aquat. Conserv. Mar. Freshwater Ecosyst. 15:259–269), tunicates and crustaceans (Amorocho and Reina 2007. Endang. Species Res. 3:43–51), hydrozoans, scyphozoans, nematodes, annelids, mollusks (Carrion-Cortez et al. 2010. J. Mar. Biol. Assoc. U.K. 90[5]:1005–1013), and sponges, *Craniella* sp. and *Suberites aurantica* (Rodriguez-Baron 2010. MS thesis. Centro Interdisciplinario de Ciencias Marinas [CICIMAR-IPN]. 98 pp.). It has been suggested that such dietary diversity is a response to the energy requirements of these animals in the early life stages, facilitating nutritional (e.g., protein) gains for development and maturation (Bjorndal 1985. Copeia 1985[3]:736–751) and optimizing digestion time (Amorocho and Reina 2008. J. Exp Mar. Biol. Ecol. 360:117–124). It has also been noted that *C. mydas* diet is influenced by resource availability (Balazs 1980. NOAA Tech. Memo. NOAA-TM-NMFS-SWFS-7; Garnett et al. 1985. Wildl. Res. 12:103–112) and that diet selection is linked to the composition and capacity of the hind-gut microflora, which may change as turtles grow and/or occupy different habitats (Bjorndal 1980. Mar. Biol. 56:147–154).

During two field trips in 2009 we collected food samples from the esophagi of 21 Green Turtles (body mass 14–65 kg, and straight carapace length [SCL ± 0.1 cm] 40.3–73.4 cm; mean SCL = 54.83 ± 8.36 cm) captured at Laguna Ojo de Liebre (LOL; 27.5833–27.9166°N, 113.9666–114.1666°W) located in the El Vizcaino Biosphere Reserve, Baja California Sur, Mexico. The anemone *Palythoa ignota* was present in 18 of the total samples, and it comprised 68.76% of the total volume. Turtle mean body condition index (BCI) was 1.48 (range = 1.25–2.06), similar to the values reported for previous studies (Koch et al. 2007. Mar. Biol. 153[1]:35–46; Seminoff et al. 2003. J. Mar. Biol. Assoc. U.K. 83:1355–1362) which indicates that animals were in good health (Bjorndal et al. 2000. Ecol. Appl. 10:269–282). To our knowledge, this is the first report of targeted anenome consumption by *Chelonia mydas agassizii*. The fact that *P. ignota* occurred in such high proportion among a substantial number (85.7%) of turtles suggests that this colonial cnidarian is a major food resource for these turtles at LOL, and that Green Turtles have the capacity to assimilate nutrients from this invertebrate species (Bjorndal 1990. Bull. Mar. Sci. 47[2]:567–570). We thank the Grupo Tortuguero de las Californias A.C. for their assistance in the logistics field work.

CHELONIIDAE (Marine Turtles). HATCHLING PREDATION. Sea turtle hatchlings are preyed on by a wide variety of predators (Stancyk 1982. *In* K. A. Bjorndal [ed.], Biology and Conservation of Sea Turtles, pp. 139–152. Smithsonian Institution Press, Washington, D.C.). However, reports of snakes preying on sea turtle hatchlings are rare. Hendrickson (1958. Proc. Zool. Soc. Lond. 130[4]:455–535.) stated that egg collectors on the east coast of Peninsular Malaysia observed mangrove snakes (*Boiga dendrophila*) and pythons (*Python reticulatus*) in the act of swallowing baby turtles (presumably *Chelonia mydas* hatchlings). LeBuff (1990. The Loggerhead Turtle in the Eastern Gulf of Mexico. Caretta Research, Inc. 216 pp.) noted a black racer, *Coluber constrictor priapus*, discovered in a *Caretta caretta* nest on the Gulf Coast of Florida but did not mention actual predation on eggs or hatchlings. Foote et al. (2000. Proc. Sea Turtle Symp. 18:189–190) mentioned the coachwhip as a predator on sea turtles on the Gulf Coast of Florida but did not provide details. Here we provide the first documentation of an Eastern Coachwhip, *Coluber* (= *Masticophis*) *flagellum flagellum*, preying on a hatchling sea turtle (apparently a *C. caretta*).

Since 1997 we have conducted sea turtle nesting surveys daily along the northern 9.7 km of Jupiter Island on the east coast of Florida in Martin Co. St. Lucie Inlet Preserve State Park comprises the northern 4.3 km of this survey area. Surveys are conducted every morning throughout the sea turtle nesting season (March–October). Three species of sea turtles (*Caretta caretta, Chelonia mydas*, and *Dermochelys coriacea*) nest every year in this area and *Lepidochelys kempii* has been documented nesting on three occasions (in 2005, 2008, and 2009). In addition to recording all sea turtle emergences, we also mark a sample of nests for the purpose of documenting nest fate and reproductive success. During the surveys, the beach is checked for hatchling tracks in an effort to document hatchling disorientation.

During the survey on the morning of 29 August 29 2010, one of us (IA) observed the tail of a *C. f. flagellum* protruding from an Atlantic Ghost Crab (*Ocypode quadrata)* burrow low on the beach at St. Lucie Inlet Preserve State Park (Fig. 1). As the burrow was approached, the snake's head appeared from an adjacent burrow approximately 30 cm to the south. As the snake emerged, a live sea turtle hatchling was observed in its jaws. The snake retracted into the burrow when approached, but reemerged after several minutes. As the snake began to emerge, a wave washed over the burrows, filling them with water and causing the snake to emerge rapidly with the hatchling still in its jaws (Fig. 2). The snake retreated quickly into the dunes, and no further observations were made. The snake was estimated to be approximately 150 cm long.

Based on direct observations and examination of photographs, the hatchling appeared to be a *C. caretta* though it would not be possible to distinguish it from a *L. kempii* or *Eretmochelys*

COLOR REPRODUCTIONS SUPPORTED BY THE THOMAS BEAUVAIS FUND

FIG. 1. Tail of a *Coluber flagellum flagellum* protruding from an Atlantic Ghost Crab (*Ocypode quadrata)* burrow low on the beach at St. Lucie Inlet Preserve State Park, 29 August 2010.

FIG. 2. *Coluber flagellum flagellum* recently emerged from an Atlantic Ghost Crab (*Ocypode quadrata*) burrow with a hatchling sea turtle in its jaws, St. Lucie Inlet Preserve State Park, 29 August 2010.

imbricata based on the observable characters. Though neither of the latter two species was documented nesting in this area during 2010, *L. kempii* nests are difficult to distinguish from *C. caretta* nests and one may have been present. Loggerheads are by far the principal species nesting in the area.

Though this is the first documentation of a *C. flagellum* preying on a sea turtle hatchling, coachwhip snakes have been documented preying on other species of turtles. Ortenburger (1928. Mem. Univ. Michigan Mus. 1:1–247) reported an unidentified turtle in the stomach of a coachwhip from the western United States and Hamilton and Pollack (1956. Ecology 37[3]:519–526) found a newly hatched *Kinosternon subrubrum* in the stomach of a 1043-mm coachwhip from Georgia. Douglas and Winegarner (1977. J. Herpetol. 11:236–238) reported remains of a *Gopherus polyphemus* from the feces of a coachwhip in Florida and Amarello et al. (2004. Herpetol. Rev. 35:178) observed a coachwhip preying on a *G. agassizii* in Arizona.

During our monitoring of sea turtle nests on Jupiter Island, it is common to see *O. quadrata* burrows in nests. Ghost Crabs are documented predators on sea turtle eggs and hatchlings (Stancyk, *op. cit.*). It is also common to see signs that hatchlings that have emerged from their nests have been dragged by ghost crabs into their burrows (pers. obs.). This is evidenced by tracks left on the beach the morning after the incident. With respect to the incident reported here, the burrows in which the snake was found were low on the beach and hatchling tracks were observed coming from a nest higher on the beach. So it appears that, in this case, the snake did not invade a turtle nest via a crab burrow but rather invaded a crab burrow containing a hatchling turtle. It was also observed that the coachwhip had two bulges in its stomach. It is unknown whether these might represent additional hatchlings, crabs, or other prey. We could find no report of coachwhips preying on crabs despite the fact that, in the beach environment, they would provide an abundant food source for a snake that is known to eat a wide variety of prey (Hamilton and Pollack, *op. cit.*) and enter burrows (Dodd and Barichivich 2007. Florida Scientist 70[1]:83–94). This might be explained by the lack of studies on coachwhips in the coastal environment despite the fact that *C. f. flagellum* is abundant in these areas (Savannah River Ecology Laboratory 2010. http://www.uga.edu/srelherp/snakes/masfla.htm).

***CHRYSEMYS PICTA BELLI* (Western Painted Turtle). MORPHOLOGY.** Additional carapace scutes (supernumerary scutes) arising from embryonic mutations have been reported in a number of turtles species (Fernandez and Rivera 2004. Biologica 59:85–88; Kazmaier and Robel 2001. Trans. Kansas Acad. Sci. 104[3–4]:178–182) but the extent of these anomalies within populations of *Chrysemys* is not well documented. We have been conducting a long-term study on the life history of *C. picta belli* at Chapman Lake near Durango, Colorado, USA (37.33010°N, 107.88677°W; WGS84) since 1994. Of the 299 individuals captured and released at this location, 13 individuals with supernumerary carapace scutes have been found to date. Of these, nine were females, three were males, and one was a juvenile of undetermined sex. In ten of the turtles (seven females and three males), the supernumerary scute was located between vertebral scute three (V3) and vertebral scute four (V4) resulting in a total of six vertebral scutes. Of the remaining three turtles, two individuals (one female and one juvenile) had six vertebral scutes with the supernumerary scute located between V4 and V5 and one individual (female) had eight vertebral scutes with the supernumerary scutes located between V2, V3, and V4.

Within this population, 4.3% of the individuals exhibited some type of carapace scute anomaly. Although the specific causes of these embryonic mutations are still unclear, a number of factors such as moisture levels during incubation (Hewavisenthi and Parmenter 2001. Copeia 2001:668–682; Lynn and Ullrich 1950. Copeia 1950:253–262), suboptimal environments, and inbreeding (Fernandez and Rivera 2004, *op. cit.*) can contribute to anomalies such as asymmetry and supernumerary scutes in turtle shells. Further research will be necessary to elucidate the underlying cause of this phenomenon within this population. Photographs available from CRC (contact information below).

***EMYDOIDEA BLANDINGII* (Blanding's Turtle). RECORD EGG SIZE.** Several turtle nesting sites on the west side of Algonquin Provincial Park in Ontario, Canada are monitored annually as

part of a long-term study. Blanding's Turtles (*Emydoidea blandingii*) are rare on the west side of Algonquin Park, with only 3 nests and 14 sightings recorded between 1959 and 2003 (Brooks et al. 2003. Reptiles and Amphibians of Algonquin Provincial Park. The Friends of Algonquin Park, Whitney, Ontario. 48 pp.). On 8 June 2010, we observed a female *E. blandingii* (24.2 cm straight line carapace length, 1810 g mass) nesting. This female laid a clutch of nine eggs, of which one egg was noticeably larger than the others (Fig. 1A). The largest egg weighed 17.0 g, and had a length of 3.94 cm and a width of 2.71 cm. This egg mass is 1.2 g greater than the largest mass previously reported for this species (Ernst and Lovich 2009. Turtles of the United States and Canada, 2nd ed. Johns Hopkins University Press, Baltimore, Maryland. 827 pp.). The other eight eggs ranged from 11.4 to 12.3 g in mass (mean ± SE = 11.6 ± 0.13 g), 3.46–3.64 cm in length (mean ± SE = 3.53 ± 0.025 cm), and 2.33–2.49 in width (mean ± SE = 2.38 ± 0.018 cm). The large egg was 14.5, 6.2, and 6.5 standard deviations larger than the mean mass, length, and width, respectively, of the other eight eggs in the clutch.

The clutch was reburied and caged *in situ* to protect the eggs from predators, and the nest was monitored daily for hatchling emergence. On 3 September 2010, nine hatchlings were observed on the ground surface under the cage. One of these hatchlings was substantially larger than the rest, and this hatchling presumably emerged from the large egg (Fig. 1B). The largest hatchling weighed 13 g, and had a straight line carapace length of 3.85 cm. The other eight hatchlings weighed 8.4–9.0 g (mean ± SE = 8.7 ± 0.08 g) and had straight line carapace lengths of 3.36–3.46 cm (mean ± SE = 3.40 ± 0.012 cm). To quantify the change in mass during development, a ratio of hatchling mass to egg mass was calculated. This ratio was found to be similar between the largest egg (0.76), and the mean for the other eight eggs (0.75).

Pelvic aperture width constraints have been suggested as an explanation for deviations from egg size/clutch size relationships predicted by optimal egg size theory in small-bodied turtle species (Congdon and Gibbons 1987. Proc. Natl. Acad. Sci. USA. 84:4145–4147; Rollinson and Brooks 2008. Oikos 117:144–151). Our observation of an anomalously large egg relative to others in the same clutch supports the idea that, at least in this case, a large-bodied turtle's egg size may not be morphologically constrained, and may still deviate from optimal egg size theory. Also, because the change in mass during development was similar regardless of size, the requirements of embryological development may not constrain egg size. Overall, our observation suggests that Blanding's Turtles may not experience the same constraints on egg size as other species. This may leave traits, such as egg, clutch, and hatchling size, free to respond to external selective pressures making Blanding's Turtles an optimal model for examining such traits.

***EMYDOIDEA BLANDINGII* (Blanding's Turtle). HATCHLING BEHAVIOR.** *Emydoidea blandingii* is a semi-aquatic emydine turtle that occupies wetland habitats in the northcentral and northeastern United States and southeastern Canada. Adults overwinter aquatically to avoid freezing and desiccation (Edge et al. 2009. Can. J. Zool. 87:824–834), but hibernacula used by hatchlings and juveniles are not well known. It has been suggested that hatchlings might overwinter in the nest cavity, in aquatic habitats, and occasionally on land outside the nest cavity (Ultsch 2006. Biol. Rev. 81:339–367), but conclusive field data are lacking.

Here we report on a putative communal terrestrial overwintering of post-emergent Blanding's Turtle hatchlings. Five individuals were found in a hollow subterranean root while conducting a radio-telemetry study of three species of hatchling turtles (*E. blandingii, Glyptemys insculpta, Chelydra serpentina*) in Algonquin Provincial Park, Ontario, Canada. Epoxy was used to attach VHF transmitters (0.55 g, Advanced Telemetry Systems [ATS], Isanti, Minnesota) to the carapace of hatchlings upon emergence from their nests. Hatchlings were tracked every 1–3 days using a 3-element Yagi antenna attached to a R410 Scanning Receiver (ATS, Isanti, Minnesota). On 17 September 2010, Blanding's Turtle hatchling #373 was tracked to the base of an alder root system but was not visually located. The location was narrowed down to a 1 m^2 area and marked with flagging tape. On 22 September, Blanding's Turtle hatchling #247 from the same clutch was tracked to the same 1 m^2 but neither turtle could be visually located despite several hours of searching through the leaf litter. After several days of not moving, the hatchlings were assumed to have been predated and cached below ground, so the area was excavated by hand to preserve any existing tunnels and animal remains. On 27 September 2010, the two hatchlings with transmitters were located alive and dormant inside a hollow root that was 14 cm in diameter and 25 cm below the soil surface. In addition, three other live Blanding's Turtle hatchlings were within 15 cm inside the same root. All five hatchlings were identified as siblings by a clutch-specific notch in their marginal scutes given at emergence on 20 August 2010. Because the turtles were observed inside the root in late fall, we presume that they had selected this site for overwintering. The root was along the border between an alder swamp and a softwood forest. This location was 63 m from their nest and it is unknown how the turtles entered the root.

There are two possible explanations for how the five sibling turtles chose the same hollow root. The first is that the hatchlings were using conspecific cues to follow each other. Although the use of chemical cues has been suggested for other species (Tuttle

FIG. 1. Five sibling Blanding's Turtle (*Emydoidea blandingii*) hatchlings in a putative hibernaculum consisting of a hollow tree root 25 cm below the soil surface. The turtles were observed on 27 September 2010.

and Carroll 2005. Northeast. Nat. 12[3]:331–348), their use has not been experimentally demonstrated for freshwater turtle hatchlings. The other possible explanation is that all five turtles were using the same cues to detect appropriate hibernacula to enter the root. Considering there were over 50 hatchlings from seven nests that hatched surrounding the wetland that fall, the probability of five hatchlings from the same clutch entering the same root without using conspecific cues would seem to be low. Although there is no experimental evidence of hatchlings following conspecific cues to reach hibernacula, our observations add to the body of evidence suggesting that chemical cues from other hatchlings are important.

The hatchlings were tracked again on 5 October 2010. The two turtles with transmitters (#s 247 and 373) were no longer inside the root and had moved 8 m and 6 m, respectively. Both hatchlings were buried in terrestrial forms, and there was no standing water at either location. The root was re-opened to check for the other three hatchlings, but none was found. It is likely that the disturbance we caused during excavation of the root system caused the hatchlings to move to a different overwintering site. However, because the hatchlings had been immobile in the root system for 5–10 days before being disturbed, we suspect that they would have overwintered in this location. Temperatures during the week of excavation were already dropping below freezing, which would have limited the mobility of hatchlings.

To our knowledge, our observations are the only known account of hatchling freshwater turtles using communal terrestrial hibernacula outside of the nest chamber, as well as the only account of Blanding's Turtle hatchlings using a hollow root system as a refuge. Future work should identify important characteristics of such sites, what cues hatchlings use to find hibernacula, and whether hatchlings can successfully overwinter in such sites.

Financial support for this work was provided by Environment Canada's Habitat Stewardship Program, the Ontario Species at Risk Stewardship Program, NSERC, and Laurentian University. In-kind contributions and financial support were provided by Algonquin Provincial Park (Ontario Ministry of Natural Resources). ***ERETMOCHELYS IMBRICATA* (Hawksbill Sea Turtle). PELAGIC JUVENILE.** *Eretmochelys imbricata* occurs throughout the tropical and subtropical oceans (Meylan and Redlow 2006. *In* P. Meylan [ed.], Biology and Conservation of Florida Turtles, pp. 105–127. Chelonian Res. Monogr. 3). In the Western Atlantic Ocean they have been observed from the southern USA to southern Brazil, throughout Central America, the Bahamas and Caribbean Sea (Meylan and Redlow 2006, *op. cit.*). After hatching, a Hawksbill undergoes a pelagic phase until attaining about 20 cm in carapace length; thereafter, it migrates to coastal regions or islands and establishes a residence, changing to a benthic phase, where it feeds and finds refuge until reaching sexual maturity (Chacón 2004. WWF-Programa Regional para América Latina y el Caribe. San José, Costa Rica). *Eretmochelys imbricata* is currently listed as Critically Endangered by the IUCN (2010. IUCN Red List of Threatened Species. Ver. 2010.4. www.iucnredlist.org), and is included in Appendix I of CITES (CITES 2005. Convention on International Trade in Endangered Species of Wild Fauna and Flora. www.cites.org/eng/append/appendices.doc).

Here we present the first record of a pelagic juvenile Hawksbill Sea Turtle in the Marine Extractive Reserve Mãe Grande de Curuçá, located in the city of Curuçá, northeast of Pará, Brazil. This individual turtle was found dead, collected, and identified by Marcela M. Ramos and verified by Marinus Hoogmoed. It was deposited in the herpetological collection of Museu Paraense Emílio Goeldi, Belém-PA, Brazil (MPEG 1068). The specimen was recovered at Romana's Beach (0.54286°S, 46.0991°W), at Guarás Island (one of 14 islands in the marine reserve), on 18 August 2010, in an "estacada" net. The "estacada" is a gillnet commonly used by fishermen in the north region of Brazil (SEPAq 2008. Diagnóstico da pesca e da aqüicultura do Estado do Pará. <http://

FIG. 1. Juvenile of *Eretmochelys imbricata* captured at Romana's Beach, Resex Marinha Mãe Grande de Curuçá, Pará, Brazil.

www.sepaq.pa.gov.br/files/u1/diag_pesca2008.php>) that can cause death in sea turtles by preventing them from surfacing to breathe (Gallo et al. 2006. Chelon. Conserv. Biol. 5:93–101). The juvenile reported here had the following measurements: 10.58 cm straight-line carapace length, 8.10 cm straight-line carapace width, 7.54 cm plastron width, 8.14 cm plastron length, 1.36 cm pre-cloacal tail length, 2.0 cm post cloacal tail length, 2.37 cm head width, and weighed 170 g (Fig. 1).

The Hawksbill Sea Turtle has an oceanic-neritic developmental pattern, characterized by early development in the oceanic zone followed by later development in the neritic zone, appearing in this latter zone at about 20–35 cm caparace length (Bolten 2003. *In* Lutz et al. 2003. The Biology of Sea Turtles. Vol. II. CRC Press, Washington, D.C.). This open ocean phase has been called the "lost years" (lasting 5–20 years) because researchers have little information on where the turtles go during this time (Miller 1997. *In* Lutz and Musick 1997. The Biology of Sea Turtles. Vol. I., pp. 51–81. CRC Press, Washington, D.C.). It has been thought that these animals may be floating among seaweed or wandering adrift in the open sea, thus the potential importance of this first occurrence of a pelagic juvenile in the neritic zone. In addition, this report highlights the importance of monitoring the incidental captures on Pará's coast, an important area for artisanal fishing (IBAMA 2004. Estatística da pesca 2002: grandes regiões e unidades da federação. IBAMA/CEPENE, Tamandaré).

We thank the Peabiru Institute for financial and logistical support during data collection. This note is part of the dissertation of M. Ramos, who thanks the UFPA and MPEG for logistical support and CAPES for fellowship support of the Master's Degree program.

***GLYPTEMYS MUHLENBERGII* (Bog Turtle). LOW INCIDENCE OF ALGAE AND LEECHES.** The interrelationships between algae and leeches and the Bog Turtle, *Glyptemys muhlenbergii*, have been essentially ignored by researchers. Major life history studies of the turtle (Arndt 1977. Chesapeake Sci. 18:67–68; Burton and Price 1955. Copeia 1955:159–165; Ernst 1977. Herpetologica 33:241–246; Holub and Bloomer 1977. Herpetol. Bull. New York Herpetol. Soc. 1:9–23) made no mention of either algae or leeches, and, apparently, no literature records of algae colonizing Bog Turtles exist. In view of this, data on algae and leech associations recorded from southeastern Pennsylvania Bog Turtles are reported here.

A total of 103 captures of Bog Turtles in a small population in Lancaster Co., Pennsylvania, USA were made from 1964–1992. The research site was described in Ernst (1971b. J. Herpetol. 5:151–160). At the time of capture, the presence or absence of algal colonies on the carapace and leeches attached to the soft parts were recorded; along with the date, plastron length, sex (Ernst and Lovich 2009. Turtles of the United States and Canada, 2nd ed. Johns Hopkins Univ. Press, Baltimore, Maryland), and other pertinent capture data (see Ernst 1971b, 1977, *op. cit.*). All turtles were notched for future identification and released.

Very few Bog Turtles were found with algae on their carapaces (5 records, 4.9% of captures). This is in direct contrast with data previously recorded for the other aquatic and semiaquatic turtles found at the site: *Chelydra serpentina*, 39.0% (Ernst et al., *in prep.*); *Chrysemys picta*, 69.1% (Ernst 1969. The Natural History and Ecology of the Painted Turtle, *Chrysemys picta* [Schneider]. Ph.D. dissertation, Univ. Kentucky, Lexington); *Clemmys guttata*, 46.4% (Ernst 1976. J. Herpetol. 10:25–33); *Glyptemys insculpta*, 17.0% (Ernst 2001. Chelon. Conserv. Biol. 4:94–99); and *Sternotherus odoratus*, 85.8% (Ernst 1986. J. Herpetol. 20:341–352). The species of algae involved was *Basicladia crassa*, a common colonizer of other turtle species, and a new host record. Although Bog Turtles were captured from March through August, algal colonies were only present on the turtles during April (4.3% of 23 captures) and May (6.3% of 63 captures). Also, algae colonization was only associated with adult males, 5 of 54 males (9.3%).

Likewise, the number of records of Bog Turtles with attached leeches was very small (4, 3.9%) compared with records from the other five species of turtles present: *C. serpentina*, 32.8% (Ernst et al., *in prep.*); *C. picta*, 10.7% (Ernst 1971a. J. Parasitol. 57:32); *C. guttata*, 12.1% (Ernst 1976, *op. cit.*); *G. insculpta*, 38.6% (Ernst 2001, *op. cit.*); and *S. odoratus*, 36.8% (Ernst 1986, *op. cit.*). As with algae, leeches were only attached to Bog Turtles during April (8.7% of captures) and May (8.7%). Three leeches were attached to adult females (6.3%), a single leech was found on an adult male (1.9%), and none was found on hatchlings or immatures; no turtle had more than one leech attached. The leech species at White Oak was *Placobdella parasitica*.

Leeches have been previously reported to parasitize *G. muhlenbergii* ("large blood sucking annelid"; Burton 1957. Our Knowledge of the Bog Turtle, *Clemmys muhlenbergi*, Further Augmented, M.S. thesis, Univ. Pittsburgh; Saumure and Carter 1998. Herpetol. Rev. 29:98; Saumure and Beane 2001. Herpetol. Rev. 32:38). Saumure and Carter (1998, *op. cit.*) found *Placobdella multilineata* on Virginia *G. muhlenbergii*, and Saumure and Beane (2001, *op. cit.*) reported both *P. multilineata* and *P. parasitica* from North Carolina Bog Turtles. Saumure and Carter (1998, *op. cit.*) noted a 52.2% incidence of *P. multilineata* attachment during June through August in Virginia, and Saumure and Beane (2001, *op. cit.*) found *P. parasitica* on 3 North Carolina female Bog Turtles in May, June, August, and September, with an average of 3 leeches per turtle. At other North Carolina sites they found 2 males and 2 females with an additional 8 *P. parasitica*. Although the total number of Bog Turtles captured was not reported, the incidence of parasitism there by *P. parasitica* seems low (2.4% on 7 turtles). In addition, Saumure and Beane (2001, *op. cit.*) found an average of 1.3 *P. multilineata* attached to 10 Bog Turtles during May and June (total number of captures not given).

In addition to the relatively small number of *G. muhlenbergii* involved in the Pennsylvania, Virginia, and North Carolina populations, the total number of leeches attached to individual turtles was also very low. In the Pennsylvania population, as many as 88 leeches have been found on individual turtles of the other species, and normally each infested turtle had more than one leech attached (see above studies cited).

Why is there such a low incidence of both algae and leech attachment for *G. muhlenbergii*? Some suggestions can be made, based on the limited data, and these relate to the microhabitat and behavior of *G. muhlenbergii* (summarized in Ernst and Lovich 2009, *op. cit.*). Essentially the species prefers very shallow, boggy sites with soft bottoms, abundant sedge (usually *Carex* sp.) tussocks or cattails (*Typha*), and numerous Meadow Vole (*Microtus pennsylvanicus*) runs. Its preferred microhabitat has been characterized as one where the Bog Turtle can "keep its feet

wet and its carapace dry." In such microhabitats the turtle forages along the shallow waterways and vole runs, and, at times of perceived danger, when becoming too warm, or at night, buries itself in the soft bottom or within the sedge tussocks. It is a confirmed basker (all age groups and sexes, although females may bask slightly more than males). Its microhabitat probably plays a major role in lowering the rate of incidence of both algal and leech attachment. Its extremely shallow water microhabitat is warmer than the cooler, deeper waters nearby, and may not be as conducive for leeches. Also, the turtle's carapace is exposed to the sun more often, even if not basking, than those of more aquatic turtles; and is thus drier and warmer (pers. obs.). Algae cells on the carapace and leeches attached to the soft parts have a greater chance of being killed by ultraviolet rays, overheating, or drying out. When not foraging or basking, the turtle is usually found under the surface of the soft bottom or within vole or Muskrat (*Ondatra zibethicus*) burrows, if available, and is then in reduced light or possibly total darkness which does not favor algae growth.

Algal and leech associations should be included in current or future ecological studies of Bog Turtles to confirm or refute the above assumptions and the apparent low incidence of colonizations.

CARL H. ERNST, Division of Amphibians and Reptiles, MRC 162, Smithsonian Institution, P.O. Box 37012, Washington, D.C. 20013-7012, USA; e-mail: chernst@frontiernet.net.

***GOPHERUS AGASSIZII* (Desert Tortoise) and *CROTALUS RUBER* (Red Diamond Rattlesnake). BURROW CO-OCCUPANCY.** I observed an adult Desert Tortoise and an adult Red Diamond Rattlesnake (sexes unknown) (Fig. 1) in a shallow tortoise burrow on 6 January 1997 at a wind energy generation facility near Palm Springs, Riverside Co., California, USA (33.9599°N, 116.6613°W). The site is located in the southeastern foothills of the San Bernardino Mountains just west of the Whitewater River. The air temperature was about 5°C at the time the photograph was taken. The burrow was located about 50 m from a row of wind energy turbines, not an unlikely location for tortoises in this population (Lovich and Daniels 2000. Chelon. Cons. Biol. 3:714–721). Both species are common at the site and Red Diamond Rattlesnakes have been seen at Desert Tortoise burrows during the summer as well. The time of year when the photograph was taken was well within the cool weather dormancy period for both Desert Tortoises (Ernst and Lovich 2009. Turtles of the United States and Canada, 2nd ed. Johns Hopkins University Press, Baltimore, Maryland) and Red Diamond Rattlesnakes (Ernst 1992. Venomous Reptiles of North America. Smithsonian Institution Press, Washington, D.C). In California the Red Diamond Rattlesnake is more commonly associated with coastal sage scrub and chaparral plant communities and the Desert Tortoise is emblematic of the desert, three very different but proximate ecosystems. Areas where the ranges of these animals overlap are comparatively small when considering their composite distributions but the transition area at the study site contains representatives of plant species from all three ecosystems. Although Desert Tortoise burrows can be occupied by many species of animals including other species of *Crotalus* (Ernst and Lovich, *op. cit.*) this is the first documented case of burrow co-occupancy for these two reptiles.

FIG. 1. *Gopherus agassizii* and *Crotalus ruber* hibernating in a shallow Desert Tortoise burrow together near Palm Springs, California, USA.

JEFFREY E. LOVICH, U.S. Geological Survey, Southwest Biological Science Center, 2255 North Gemini Drive, MS-9394, Flagstaff, Arizona 86001, USA; e-mail: jeffrey_lovich@usgs.gov.

***GOPHERUS POLYPHEMUS* (Gopher Tortoise). BURROW ASSOCIATE.** *Gopherus polyphemus* excavate and inhabit burrows in xeric, sandy habitats of the southeastern United States (Auffenberg and Franz 1982. *In* Bury [ed.], North American Tortoises: Ecology and Conservation, pp. 95–126. USDI Fish and Wildlife Service, Wildl. Res. Rep. 12). Because of the cool, moist microenvironment provided by tortoise burrows, a number of animals use them as refugia with 60 vertebrate and 302 invertebrate species documented utilizing burrows (Jackson and Milstrey. 1989. *In* et al. [eds.], Proceedings: Gopher Tortoise Relocation Symposium, pp. 86–98. Florida Game and Fresh Water Fish Commission, Tallahassee, Florida). Although the Six-lined Racerunner (*Aspidoscelis sexlineata*) has been observed using tortoise burrows for refuge, it has never been reported to nest in tortoise burrows or the burrow aprons, the mound of excavated sand deposited outside the burrow entrance. Here we present six instances of *A. sexlineata* nesting in the aprons of burrows of *G. polyphemus* at the Aiken Gopher Tortoise Heritage Preserve, Aiken Co., South Carolina, USA.

In the course of searching for and excavating *G. polyphemus* nests on 25 August and 1 September 2010, we unearthed six *A. sexlineata* nests at six separate burrows. All nests were buried shallowly on burrow aprons. Four of the nests consisted of neonates emerging from or recently emerged from eggs, while two nests contained clutches of two and three eggs each. We brought the clutch of two eggs to the laboratory where it subsequently hatched on 3 September (eight days later). Tortoise burrows have long been acknowledged as important microhabitats within open-canopied, sandy habitats for species seeking thermal refugia, moist hides, or foraging areas (Milstrey 1986. *In* Jackson and Bryant [eds.], The Gopher Tortoise and its Community, pp. 4–25. Proceedings 5th Annual Meeting Gopher Tortoise Council, Florida State Museum). Female Gopher Tortoises are also known to nest in the aprons of their burrows; however, these observations of *A. sexlineatus* highlight the potential for the aprons of Gopher Tortoise burrows to serve as important oviposition sites for other herpetofaunal species.

***KINOSTERNON SUBRUBRUM* (Eastern Mud Turtle) MUSKING.** Many turtle species have externally secreting musk glands located in the bony bridge region that binds the plastron with the carapace. These glands are referred to as Rathke's glands, and their pores are generally located on the axillary and inguinal scutes (Ehrenfeld and Ehrenfeld 1973. Copeia. 1973:305–314). The number of glands varies from one to three (pairs) in extant species and up to four pairs in fossil turtles. The discovery of four pairs of Rathke's glands in *Kayentachelys aprix* from the North American early Jurassic (150 mya) suggested that turtles were among the first amniotic lineages to evolve skin glands (Weldon and Gaffney 1998. Naturwissenschaften 85:556–557). The purpose of Rathke's glands is not clearly understood, but the most common explanation is that they function as a predator deterrent, though this assertion has not been proven experimentally. Laboratory experiments focusing on the musk turtles (Kinosternidae: *Sternotherus*) suggested that Rathke's gland secretions function in mating behavior, but the effects of other chemical secretions could not be ruled out (Lewis et al. 2007. J. Herpetol. 41:349–353).

The secretion of musk or "musking" may be regulated in relation to the situation at hand. During predator deterrence musk could be secreted indiscriminately as a negative stimulus to the attacker. In intraspecific communication, a female may signal to a male that she is receptive, or a male may signal as a warning to another male of its presence. I use this reasoning to explain observations of differential musk secretion in 10 Eastern Mud Turtles (*Kinosternon subrubrum*) collected from forested floodplains and freshwater tidal marshlands of the Patuxent River in Maryland, USA (38.7839°N, 76.7093°W). Five adult males and five adult females were hand-captured, and marked in upland forests during April of 2008. All turtles excreted musk prominently when handled. Malodorous secretions accumulated and streamed from the surface of the axillary and inguinal scutes in up to three sizable drops. The turtles were then released at their exact capture locations in upland forests. When the original 10 turtles were recaptured in aquatic habitats (>5 recaptures/individual) in May–August, musk secretion was not observed, or at least was not appreciable. To test whether this lack of musk secretion was the result of acclimation to frequent human intrusion, an additional seven adult turtles were captured in water. Musk secretion in these individuals was not detected. It is feasible, but seemingly unlikely, that musk may not have been detected due to its being diluted by water.

I speculate that musking in *K. subrubrum* may not serve as an efficient anti-predatory strategy in the aquatic environment for at least two reasons (in addition to a possible dilution factor). First, gland pores may be blocked by debris that accumulates on the shell of this bottom-walking species. I observed that, in many cases, the entire plastron and marginal carapace was covered by a thick layer of algae or mud. Secondly, excessive musk secretion might advertise the presence of an individual to predators, and competitors of the same or different species. Kinosternid turtles are prey to larger bottom-walking chelydrids. Experiments have shown that *Sternotherus* is capable of using chemosensory cues to detect the presence of *Macroclemys temminckii*, but the reciprocal was not shown (Jackson 1990. Copeia 1990:557–560). It is thus possible that kinosternids may be able to use chemosensory cues to detect conspecifics. Aggressive behavior towards conspecifics in *K. subrubrum* can be severe while in water (Rigley 1973. Bull. Maryland Herpetol. Soc. 10:22–23). Therefore, it might be advantageous to regulate musk secretion in order to minimize detection. There is a modest body of evidence to suggest that turtles are capable of aquatic chemoreception in inter- and intraspecific interactions (reviewed in Polo-Cavia et al. 2009. Biol. Invas. 11:431–440). Based on my observations, *K. subrubrum* may tend to musk in the terrestrial environment to deter predators, but may reduce use of musk glands in the aquatic environment for reasons that remain speculative. For instance, in kinosternids or other turtle species, it is not clear whether Rathke's glandular secretions follow seasonal patterns. As such, the function of these glands remains obscure, and aspects of its behavioral and chemical ecology warrant further examination (Plummer and Trauth 2009. Herpetol. Cons. Biol. 4:207–220).

These observations were made while conducting research at the Jug Bay Wetlands Sanctuary in Lothian, Maryland. I thank Chris Swarth, Sanctuary Director, for logistical assistance, and the Friends of Jug Bay for funding.

***PODOCNEMIS UNIFILIS* (Yellow-spotted River Turtle). NEST PREDATION.** In some localities, ants are considered important predators of turtle nests (Fachín-Terán 1994. Boletín de Lima 16:417–423; Moulis 1997. Chelon. Conserv. Biol. 2:433–436). However, the level of this impact is still poorly understood and rarely documented (Caut et al. 2006. Can. J. Zool. 84:908–915). Here we report on the impact of ants on the reproductive success of the freshwater turtle *Podocnemis unifilis* at a site in the Brazilian eastern Amazon.

Between 22 September and 27 December 2009 we daily monitored nests of *Podocnemis unifilis* at a 29.68-ha study site at Taboleiro da Água Preta (02.0912°N, 054.3717°W), western Pará State, Brazil. This site is a floodplain area in the lower Amazon River, near its confluence with the Tapajos River. Of the monitored nests, 1.2% (two nests) were partially predated by the fire ant *Solenopsis saevissima* (Formicidae: Myrmicinae). In the first depredated nest of 34 eggs, four hatchlings (11.8%) were lost to ants, and in second nest, also with 34 eggs, 14 hatchlings (41.2%) were predated.

The level of ant predation seemingly can vary widely between even closely spaced nests; for example, 52.4% of nests at a site in the Peruvian Amazon (Fachín-Terán, *op. cit.*), 8.3% in Georgia, USA (Moulis, *op. cit.*), and only 1.2% in the Brazilian eastern Amazon (this study). However, it is not yet known which factors might influence the probability of predation of turtle nests by ants. Future studies should better define the impact of ants on the nesting success of turtles.

We thank the FAPESPA, UFPA, and MPEG for financial and logistical support during data collection and acknowledge the assistance of I. P. Santos in the English translation of this work. M. Pignati and W. Dáttilo were supported by master's degree fellowships from CNPq and CAPES, respectively.

***PSEUDEMYS CONCINNA SUWANNIENSIS* (Suwannee Cooter). FISH PREDATION.** Fish predation on turtles is well known, but some large carnivorous fishes such as the Bowfin (*Amia calva*) have not been considered turtle predators (Ernst et al. 1994. Turtles of the United States and Canada. Smithsonian Inst. Press, Washington, D.C. 578 pp.; Jordon and Arrington 2001. Wetlands 21:155–159). On 4 May 2010 at the 0300 h we captured an adult female *A. calva* (812 mm total length, 4082 g) in Ginnie Spring (29.8361°N, 82.6997°W), High Springs, Florida, USA. While dissecting this specimen, we found a juvenile *Pseudemys concinna suwanniensis* (39 mm straight midline carapace length, 37 mm straight midline plastron length, 33 mm carapace width, 17 mm height) in the stomach contents. This observation might be the first record of turtle predation by *A. calva* and also expands the list of predators potentially influencing populations of *P. c. suwanniensis*, which is listed by the Florida Fish and Wildlife Conservation Commission as a Species of Special Concern.

JOHNSTON,** Department of Natural Sciences, Santa Fe College, Gainesville, Florida 32606, USA (e-mail: jerry.johnston@sfcollege.edu).

***STERNOTHERUS CARINATUS* (Razor-backed Musk Turtle). PREDATION.** On 6 June 2008, seven *Sternotherus carinatus* shells, one *Apalone spinifera* and *A. mutica* shell each, and several catfish (*Ictalurus* sp.) skulls were found on the ground below a Bald Eagle (*Haliaeetus leucocephalus*) nest on Kincaid Lake, Rapides Parish, Louisiana, USA.

All of the *S. carinatus* shells apparently are of adult size, and averaged 136.1 mm in carapace length (111.3–144.0 mm), 91.8 mm in carapace width (80.8–99.3 mm), 96.5 mm in plastron length (79.2–104.1 mm), and 59.7 mm in shell height (50.1–69.3 mm). The shells remained mostly intact and were all that remained of the turtles except for a few attached vertebrae and limb bones. This is the first report of a specific, non-human predator for adults of this species (Ernst and Lovich 2009. Turtles of the United States and Canada, 2nd ed. Johns Hopkins University Press, Baltimore, Maryland. 827 pp.; Lindeman 2008. Chelon. Res. Monogr. 5:012.1–012.6; Mahmoud 1969. Southwest. Nat. 14:31–66). There are, however, reports of Bald Eagles preying on the congeneric *S. odoratus* (Clark 1982. J. Field Ornithol. 53:49–51; Ernst and Lovich 2009, *op. cit.*) and both species of *Apalone* (Watermolen 2004. Bull. Chicago Herpetol. Soc. 39:69–70).

Voucher specimens are deposited in the University of Louisiana at Monroe Museum of Natural History: *Apalone mutica* (NLU 70630), *A. spinifera* (NLU 70629), and six of the seven *S. carinatus* (NLU 70631–70636). Turtles specimens were collected with LNGP permit #2008–043.

CARR,** Department of Biology and Museum of Natural History, University of Louisiana at Monroe, Monroe, Louisiana 71209-0520, USA (e-mail: carr@ulm.edu).

***TERRAPENE CAROLINA CAROLINA* (Eastern Box Turtle). AGGRESSION / REPRODUCTION.** On 25 September 2010, on the campus of Messiah College (Grantham, Pennsylvania, USA; 40.1564°N, 76.9964°W), the interactions of two male and one female *Terrapene c. carolina* were observed. When they were first encountered, one of the males (designated α) was copulating with the female (♀) (phase 3) and the other male (designated β) was alternating between biting the front of the carapace and attempting to mount her (phase 1). (Note: these three phases of box turtle courtship and mating were described by Evans [1953. Herpetologica 9:198–192] as circling/biting/shoving [phase 1], mounting [phase 2], and copulating [phase 3]). Interestingly, neither male responded to the other's presence. α remained motionless in a typical phase 3 posture, and β made no attempts to dislodge him, but continued normal phase 1 behavior as if α was not there. The ♀ had the front of her plastron partially open, but she did not extend her head or limbs. This continued for 20 minutes, then α and the ♀ separated, and α righted himself. The ♀ began to rapidly leave, and both males chased after her, biting at each other's necks as they ran. β ran ahead of α. After a short distance, the ♀ stopped and partially closed up. Both males stopped as well, but they kept their necks stretched out. β bit the rear of the ♀'s carapace several times, then turned away from her and approached α. He stopped before reaching α, pushed himself up on his legs, and repeatedly raised and lowered his left front leg. This behavior, however, is typical of a male courting a female, not of a male fighting another male (Evans 1953, *op. cit.*). Other researchers have observed males trying to mate with other males (Harless and Lambiotte 1971. J. Biol. Psychol. 13:17–23). α did not appear to make any response to β. After seven minutes, the ♀ began to leave again. As soon as she moved, both males extended their necks even further, looked in her direction, and then chased after her. The ♀ stopped and closed her shell after moving a short distance. β was immediately behind her, and α was immediately behind him. This time, α continued to charge forward, and β turned 90° to the left and confronted him. α lunged at the front of β, and β immediately closed up. α bit at β several times, then walked off. After α had moved roughly 0.5 m, β opened up and charged after him. It was unclear whether this chasing was aggression or courting, but it is interesting that β left the ♀ who was sitting motionless beside him. As β approached, α turned 180° and lunged at β. Once again, β closed up immediately. This time, however, α stayed and continued to bite at β whenever β opened his plastron. Ten minutes later, the ♀ opened up and moved away. β was closed during her departure, and α was open and facing the ♀, but he did not chase after her.

It is possible that α may have been mate guarding; however, female Eastern Box Turtles can store sperm for several years, and it would presumably be inefficient for a species with delayed fertility to also exhibit mate guarding (Ewing 1943. Copeia 1943:112–14; Gist and Fischer 1993. J. Reprod. Fertil. 97:463–468). In defense of a mate guarding hypothesis, however, Tonge (1987. Dodo, J. Jersey, Wild. Preserv. Trust 24:111–120) reported that in a group of captive Aquatic Box Turtles (*Terrapene coahuila*) one dominant male prevented the other males from mating.

It might be possible to attribute most of the observed behaviors to the tendency of *Terrapene carolina* to respond to movement (Fitch 1965. Trans. Kansas Acad. Sci. 68:522–532). Male Box Turtles have been known to totally ignore a female that is immobile, but readily investigate a moving, turtle-shaped object (Belzer 2002. Turtle and Tortoise Newsl. 6:17–26). This may indicate that the various instances of α and β responding to each other and ignoring the ♀ were simply a result of the fact that the other male was moving, and the ♀ was not.

DONALD T. McKNIGHT, 1161 Priestford Road, Street, Maryland 21154, USA; e-mail: dm1303@messiah.edu.

CROCODYLIA — CROCODILIANS

***CROCODYLUS PALUSTRIS* (Mugger Crocodile). SIGNALING BEHAVIOR.** Although *Crocodylus palustris* is a common and well-studied species, the signaling behavior of adults during the mating season has never been studied. Observations on *C. palustris* were made during the mating season at three locations in India: in the wild in Sasan Gir National Park (Gujarat, 21.13°N, 70.78°E, January 2007) and Katerniaghat Wildlife Sanctuary (Uttar Pradesh, 28.34°N, 81.42°E, March 2007), and in captivity in Madras Crocodile Bank (Tamil Nadu, 12.74°N, 80.25°E, December 2006). At the first two locations, the crocodiles inhabited rivers of varying size and small forest ponds. At the third location, they were kept in concrete ponds within bare-ground enclosures.

Observations in the wild were conducted *ad libitum* by locating large individuals (the most likely to be males) and watching them and other crocodiles in view from a distance of at least 50 m. At each location, continuous 24-h observation was initially attempted to determine the approximate time of day when signaling behavior was most likely to occur. As soon as that time period was determined, observational efforts were concentrated with that time frame. At Madras Crocodile Bank, the animals were observed from 1600 to 1200 h, with two 5-min breaks.

The crocodiles produced roars and headslaps, performed in arched-back posture at the water's edge, and these behaviors were accompanied with body vibrations and "water dance" effects indicative of infrasound pulse, as described for the Nile Crocodile (*C. niloticus*) and the American Crocodile (*C. acutus*) (Garrick et al. 1978. Bull. Am. Mus. Nat. Hist. 160:153–192). Mugger roars are similar to those of Nile Crocodiles (pers. obs.), but louder (audible to a human observer at more than 1 km under ideal conditions) and longer (up to five sec in duration, as seen on spectrograms). Unlike Nile and American crocodiles (Dinets, in prep.), roars were used more frequently than headslaps; eight roars vs. two headslaps at Katerniaghat (in five days of observation), six roars vs. three headslaps at Sasan Gir (in seven days of observation), and one roar at Madras Crocodile Bank (in one day of observation).

Roaring on land was not observed in wild individuals, however, the only roar observed at Madras Crocodile Bank was produced by a male on land. Two smaller crocodiles (probably females) immediately approached the male and initiated courtship behavior (chin touching).

All roars and headslaps were produced by animals more than 2 m long (by visual estimate), and never by animals known from mating observations to be females. In most cases, roars and headslaps were produced within one hour before or after sunrise, and before the animals left the water to bask onshore. The only exceptions were the abovementioned roar on land and one roar in the water, produced by a male in Sasan Gir three hours after sunrise, following two hours of basking onshore on an exceptionally cold morning (minimum air temperature 11°C). Another male at the same location once produced a roar without an arched-back display immediately after (and possibly in response to) a roar by a lion (*Panthera leo*) half an hour before sunrise. In both cases the sex of each individual was known from observed matings.

I thank Gaurav Bhatnagor, Dabeer Hasan, Krishna Kumar Mishra, Pradeep, Kabir Sharma, Gopi Shindar, Nikhil Whitaker, and Romulus Whitaker for assistance, advice, and access to permits.

VLADIMIR DINETS, Department of Biology, University of Miami, Coral Gables, Florida 33146, USA; e-mail: dinets@gmail.com.

***MELANOSUCHUS NIGER* (Black Caiman). SIGNALING BEHAVIOR.** Observations presented herein on *Melanosuchus niger* were made between 15–19 August 2008 in Rupununi River and an adjacent oxbow lake near Karanambu Ranch, Region 9, Guyana (3.75°S, 59.26°W), and on 21–22 December 2010 at Laguna Añangucohoa in Yasuni National Park, Orellana Province, Ecuador (0.55°S, 76.45°W). In Guyana, three caimans were observed from shore or boat for one 16-h period each, from one hour before sunset to three hours after sunrise. In Ecuador, one caiman was observed from shore for three 11-h periods, from one hour after sunset to sunrise. During each observation period there was only one caiman in sight. The minimum observation distance was 50 m. The animals did not show any sign of disturbance or awareness of the observer's presence. No artificial light was used because moonlight was sufficient for observation (full moon on 16 August 2008 and on 21 December 2010). All caimans were visually estimated to be 3–3.5 m long. Animals of that size were most likely adult males (Herron 1991. Biol. Conserv. 55:103–113).

The animals performed roaring and head-slapping displays in arched-back posture, as described for the American Alligator (*Alligator mississippiensis*) (Garrick et al. 1978. Bull. Am. Mus. Nat. Hist. 160:153–192; Vliet 1989. Am. Zool. 29:1019–1031). Two roaring and four head-slapping displays were observed in Guyana; one roaring and two head-slapping displays in Ecuador. To a human observer, Black Caiman roars sound similar to roars of Spectacled (*Caiman crocodylus*), Yacare (*C. yacare*), and Broad-snouted (*C. latirostris*) caimans (pers. obs.), but are louder (probably audible at more than 300 m in ideal conditions) and longer (estimated to last for 1–1.5 sec). Body vibrations and "water dance" effect indicative of infrasound production (Garrick et al., *op. cit.*) accompanied all displays. All signaling behavior was observed at night (between 1 h after sunset and 20 min before sunrise).

Black Caimans breed during the rainy season: August in Guyana (Peter Taylor, pers. comm.) and in June in Ecuador (Serverio Pachac, pers. comm.). The observations in Ecuador were made during a two-week period of exceptionally heavy rains; this probably explains why the animal was displaying outside the mating season. To my knowledge, signaling behavior of the Black Caiman has never before been described in literature.

I thank Mariela Cardenas, Serverio Pachac, Peter Taylor, and the McTurk family for their assistance in this study.

VLADIMIR DINETS, Department of Biology, University of Miami, Coral Gables, Florida 33146, USA; e-mail: dinets@gmail.com.

***MELANOSUCHUS NIGER* (Black Caiman). LONG DISTANCE MOVEMENT.** The Black Caiman (*Melanosuchus niger*) is the largest of the four crocodilian species found in the Amazon River basin. Despite its economic and ecological importance, relatively little is known of its ecology and behavior (Vasquez 1991. Cat. Amer. Amphib. Rept. 530.1–530.4). Commercial hunting for caiman skins was common throughout the Amazon until the 1960s (Smith 1980. Biol. Conserv. 19:177–187) and in Brazil it was prohibited in 1967. However, over the last 20 years, *M. niger* populations have been recovering in many parts of the species' range, and today it is abundant in many parts of Brazilian Amazonia (Da Silveira 2002. *In* Larriera and Verdade [eds.], La Conservación y el Manejo de Caimanes e Cocodrilos de América Latina, pp. 61–78. C. N. Editoria, Piracicaba, São Paulo, Brazil).

As part of an evaluation of the Black Caiman population in the Mamirauá Sustainable Development Reserve (1,124,000 ha) in the western Brazilian Amazon (Da Silveira et al. 2008. Copeia

2008:425–430), we captured adults and subadults for a radio-telemetry study of movement patterns. Caimans were captured at night using a pole with a breakaway noose from a 4.7-m aluminum boat with a 15-hp motor (Da Silveira and Da Silveira 1997. Newsletter Crocodile Specialist Group – IUCN/SSC 16[2]:18–20). Caimans were marked by a monel toe web tag attached at the right rear foot and equipped with Advanced Telemetry Systems (ATS) transmitters (164 MHz) fixed with Kevlar® line to the dorsal surface of the tail between the double rows of caudal scutes, immediately anterior to the single scale row of caudal scutes (Da Silveira et al. 2010. J. Herpetol. 44:418–424).

On 26 September 1997, we captured a small adult male *M. niger* (167 cm SVL, 335 cm TL and 98 kg) in Lago Mamirauá (02.9847°S, 064.9167°W). After capture the caiman was marked, radio-equipped, and released one hour later. The radio-equipped male was located on 62 occasions between its capture and 24 April 1999 (= 580 days). Sixty percent of the subsequent movements were of ≤ 100 m, 76% were ≤ 500 m and 11% were between 2400 and 3900 m (mean = 614; SD = 887), totaling at least 38.1 km.

The *M. niger* used two core areas, a dry season core range in Lago Mamirauá and a wet season core range in Lago Acácio, an intermittent water body adjacent to Lago Mamirauá that dries entirely during the dry season. The Lago Mamirauá core area was composed of 16 locations between 57 and 1400 m (mean = 664, SD = 348) from the release site. Forty locations formed the Acácio core area, which had its center located 4.7 km from the capture site. After 29 April 1999 we lost the radio signal and assumed that the transmitter's battery had run out.

Four years and seven months later, on 1 December 2003, the male was killed in the Lago Atapi (02.8796°S, 064.6388°W) in the Amanã Sustainable Development Reserve, 33 km (straight-line distance) NE from the original capture site and 33.8 km (straight-line distance) from the last observed location in Lago Acácio. The caiman was killed by people from the community of Nova Jerusalém, and it was detected by the Hunting Monitoring Program of the Mamirauá and Amanã Reserves. The radio-transmitter and the monel toe web tag were still attached to the animal's body. At that time, the Black Caiman measured 380 cm (TL) and produced 60 kg of dried, salted meat for sale, probably to Colombian traders, a practice common in the upper Amazon River (called Solimões in Brazil) during the 1990s (Da Silveira and Thorbjarnarson 1999. Biol. Conserv. 88:103–109). Other body characteristics were not available, but we estimated an approximate SVL of 186.5 cm and weight of ca. 117 kg (Mendonça 2009. A Caça Comercial de Jacarés no Baixo Rio Purus e suas Implicações no Manejo Sustentável na Reserva Piagaçu-Purus, Amazônia Central. Unpubl. Masters thesis. Instituto Nacional de Pesquisas da Amazônia/Universidade Federal do Amazonas. Manaus, Amazonas, Brazil. 52 pp.).

Movements between the Mamirauá and Amana Reserves have also been reported for the Amazonian Manatee (*Trichechus inunguis*) (Arraut et al. 2009. J. Zool. 2009:1–10), and for the Six-tubercled Amazon River Turtle (*Podocnemis sextuberculata*) (Fachín-Terán 1999. Ecologia de *Podocnemis sextuberculata* (Testudines, Pelomedusidae), na Reserva de Desenvolvimento Sustentável Mamirauá, Amazonas, Brasil. PhD thesis. Instituto Nacional de Pesquisas da Amazônia/Universidade Federal do Amazonas. Manaus, Amazonas, Brazil. 189 pp.). All three species are commonly hunted for subsistence or illegal commercial trade in the Mamirauá and Amanã Reserves, and *M. niger* meat is also used as bait for *Calophysus macropterus*, a pimelodid catfish sold in Colombian markets (Da Silveira and Viana 2003. Crocodile Specialist Group Newsletter 22:16–18). Although movement patterns of *M. niger* are unknown aside from the data provided here, such a long-distance movement was unexpected.

Together, the Mamirauá and the Amanã Reserves comprise an area of 3,474,000 ha, representing an enormous and contiguous block of protected Amazonian habitats. The movement of the *M. niger* between these reserves reinforces the ecological importance of megareserves (> 1 Mha) for the effective conservation of populations of Amazonian top predators.

THORBJARNARSON**†, Wildlife Conservation Society, Gainesville, Florida. †deceased February 2010.

SQUAMATA — LIZARDS

***AMBLYRHYNCHUS CRISTATUS* (Galápagos Marine Iguana). PREDATION.** On 18 December 2003, GM observed a large male Galápagos Sea Lion (*Zalophus wollebaeki*) prey on an adult-sized (>23 cm SVL) *Amblyrhynchus cristatus* at Bahia Paraiso on the island of Santa Fe, Galápagos (90.028°W, 0.829°S, datum: WGS84, elev. <1 m). The iguana was captured while walking on land 3 m from the shoreline, bitten at the base of the tail, and shaken back and forth for about 1 min in a manner similar to that employed by sea lions when preying on large fish (Everitt et al. 1981. Murrelet 62:83–86). The iguana was then bitten several more times and swallowed whole. Two additional predatory episodes were observed during the same morning, involving the same male sea lion biting and shaking adult-sized iguanas, but we were unable to observe whether these individuals were also consumed. Galápagos Sea Lions are frequently found in the vicinity of marine iguanas, but predation on iguanas has not previously been observed. Galápagos Marine Iguanas are thought to have evolved in the absence of terrestrial predators; this is the first record of predation on adult marine iguanas by any native predator that uses terrestrial habitat at least some of the time.

VITOUSEK, Department of Ecology and Evolutionary Biology, Princeton University, Princeton, New Jersey 08544, USA, and (current address) Department of Ecology and Evolutionary Biology, UCB 334, University of Colorado, Boulder, Colorado 80309, USA (e-mail: vitousek@colorado.edu); **GABRIELA MALDONADO,** Departamento de Biologia, Pontificia Universidad Católica del Ecuador, Apartado 17-01-2184, Quito, Ecuador.

***AMEIVA AMEIVA* (Giant Ameiva). PREDATION.** Despite its extensive distribution in South America (Vitt and Colli 1994. Can. J. Zool. 72:1986–2008) with various aspects of its natural history described (Colli 1991. Copeia 1991:1002–1012), there are few known predators for *Ameiva ameiva* (Martins and Oliveira 1998. Herpetol. Nat. Hist. 6: 78–150). Hence, we add to the limited data on *A. ameiva* predators with an observation of predation by Gray Hawk (*Buteo nitidus*).

On 16 June 2008, while conducting an ornithological survey as a part of the monitoring study of the Faxinal II Hydroeletric Power Plant in Mato Grosso state, Brazil, we collected an adult *B. nitidus* with a pressure gun from a grassland area of Aripuanã,

MT (10.108611°S, 59.410556°W, datum: WGS 84). Dissection revealed one adult *A. ameiva* in the stomach. Grasslands were surrounded by rain forest dominated by Brazilian Nut Tree (*Bertholletia excelsa*).

Buteo nitidus hunts in open woods, grassland, and edges of rainforest to dry open areas with scattered trees (Collins 2006. Field Guide to the Birds of South America: Non-passerines. p. 134., Harpercollins Pub. Ltd., Hammersmith, London). This species is known to prey on rats, snakes, lizards, and insects (Sigrist 2006. Aves do Brasil: Uma visão artística. Editora Avis Brasilis. São Paulo. 413 pp.), but to our knowledge, none of the lizards recorded as prey were identified to species.

The *B. nitidus* specimen (#1765; collection license 10698-1/SISBIO/IBAMA) (length: 37.5 cm; weight: 470 g) and its stomach contents were deposited in Laboratório de Ornitologia, Campus of Cuiabá, Universidade Federal de Mato Grosso (UFMT). We thank PASCON for logistical support and Robson W. Ávila for lizard identification.

***AMEIVA AMEIVA* (Giant Ameiva). PREDATION.** *Ameiva ameiva* is widely distributed in the Americas (Vitt and Colli 1994. Can. J. Zool. 72: 1986–2008), usually associated with forest edges, along waterways where the canopy is absent, and in a myriad of disturbed habitats (Vitt et al. 2008. Guide to the Lizards of Reserva Adolpho Ducke, Central Amazonia. Áttema Design Editorial. 176 pp.). Records of predation on *A. ameiva* exist for snakes (Bernarde and Abe 2010. Biota Neotrop.10:167–173; Fischer and Gascon 1996. Herpetol. Rev. 27:204; Granzinolli et al. 2007. Herpetol. Rev. 38:448–449; Santos and Germano 1996. Herpetol. Rev. 27:143), birds (Batista de Pinho et al. 2010. Herpetol. Rev. 41:72; Tozetti et al. 2005. Herpetol. Rev. 36:443–444) and wild or domestic felines (Urich 1931. Trop. Agric. 8:95–97).

On 7 July, 2007, at 1428 h, we observed predation on *A. ameiva* by the Brown-nosed Coati (*Nasua nasua*) on an unpaved road from a private farm located in Pantanal, municipality of Miranda, Mato Grosso do Sul State, central Brazil (San Francisco farm; 20.086369°S, 56.616061°W, WGS84). The coati chased the lizard before capturing it, held it with its front paws, and then began biting the head. The lizard, a juvenile ca. 25 cm snout–vent length, died approximately 15 sec. after being captured. Total time taken for the coati to completely ingest the lizard was not possible to estimate, due to an approaching vehicle, which scared off the animal, however, more than one minute was spent ingesting the head. Our observation includes *N. nasua* as an addition to the known predators for *A. ameiva*.

The Brown-nosed Coati, is distributed in South America from northern Colombia to northern Argentina. It is diurnal, scansorial, and omnivorous, feeding mainly on invertebrates and fruit (Beisiegel 2001. Braz. J. Biol. 61:689–692; Gompper and Decker 1998. Mamm. Species 580:1–9). When present in the stomachs and/or intestinal contents, vertebrates generally make up a small percentage of the diet for these animals (Alves-Costa et al. 2004. J. Mammal. 85:478–482; Bisbal 1986. Mammalia 50:329–339; Santos and Beisiegel 2006. Rev. Bras. Biociênc. 8:199–203).

CAMILA AOKI (e-mail: aokicamila@yahoo.com.br), **LILIANA PIATTI, PAULO LANDGREF-FILHO,** Programa de Pós Graduação em Ecologia e Conservação. ***AMPHISBAENA MERTENSI* (NCN) HABITAT.** Many aspects of the natural history of amphisbaenians are difficult to observe due to their fossorial habits (Gans 1978. Trans. Zool. Soc. Lond. 34:347–416). In Brazil, few observations or studies regarding the natural history of these reptiles have been made *in situ*, and available observations on their biology have been recorded through opportunistic encounters (Sazima and Haddad 1992. *In* L. P. C. Morellato [ed.], Historia Natural da Serra do Japi. Ecologia e Preservação de uma área Florestal no Sudeste do Brasil, pp. 212–237. Editora da Universidade Estadual de Campinas, Campinas) or obtained from captive animals (Torres 2003. Notes Fauniques de Gembloux 53:63–69).

Between the months of January and December, 2007, we observed *A. mertensi* foraging in garbage at a residence in the city of Maringá, Paraná State, Brazil (23.4100°S, 51.9497222°W). The observations were of both diurnally and nocturnally active individuals on the following dates and times: 20 April at 1700 h, 1 May at 1800 h, 19 July at 1636 h, 22 July at 1542 h, 24 October at 2432 h, and 19 November at 1709 h. Some of these observations included two to three individuals. Voucher specimens were collected and deposited at the Laboratory of Zoology of Faculty Uningá (17a–c). During January, several *A. mertensi* were found run over on the street, always close to garbage bags. January had high rainfall (271.5 mm), and we noted that during the rains this species disperses over the ground surface. The largest number of individuals was observed in late afternoon and in early morning, as is also recorded for *A. alba* (Abe and Johansen 1987. J. Exp. Biol. 127:159–172; Sazima and Haddad 1992, *op. cit.*). In the remaining months of the year, individuals of *A. mertensi* were often found in yards or inside residences. The animals appeared to be attracted to the garbage from these residences. On some occasions we observed individuals (N = 3) pulling the used oiled paper from fried cooking out of the garbage bags. This behavior may be associated with foraging for small invertebrate prey upon which this species feeds (Cruz Neto and Abe 1993. J. Herpetol. 27:239–240; Pramuk and Alamillo 2003. Herpetol. Rev. 34:221–223); the odor of fried oil attracted various Diptera and Hymenoptera to the oiled paper. On one occasion we offered the amphisbaenian fried beef meat and raw poultry meat, but it showed no interest. The fossorial ecology of this amphisbaenian has allowed it to remain in disturbed areas, where it appears to now be implementing opportunistic foraging behavior within these new conditions.

We thank Hélio R. da Silva, Mirco Solé, and Alexandre Aschenbrenner for reading and offering suggestions on the manuscript.

***ANOLIS LAEVIVENTRIS* (NCN). DEFENSIVE BEHAVIOR.** The behavior of "playing dead" is referred to as tonic immobility and is present in many species throughout the animal kingdom, perhaps most prominently observed in the Virginia Opossum (*Didelphis virginiana*), which famously "plays possum" (Hoagland 1928. J. Gen. Physiol. 11:715–741). Tonic immobility has been observed and studied in *Anolis carolinensis*, which readily displays

dorsal immobility (Webster et al. 1981. Behav. Neural Biol. 31:32–41), and *A. sagrei* (Regalado 1985. Ciencias Biológias 14:33–48). Similar behavior has also been observed in some Lesser Antillean anoles including *A. barbouri* and *A. oculatus winstoni* (Robert Hoogveld, pers. comm.). Hoagland (*op. cit.*) described the process of dorsal immobilization as placing the anole in the dorsal position and applying slight force to its thorax. This is similar to tonic immobility, except that it involves inverting the individual onto its dorsum before or during restraint.

On 26 May 2010, at Finca Haciendo Monimbó (Matagalpa Department, Nicaragua), two specimens of *Anolis laeviventris* were observed exhibiting tonic immobility, presumably as a defense mechanism. This behavior was observed around 2200 h with no natural lighting present. Upon capture, the individuals struggled to escape the grasp of one of the authors (JGP), and then suddenly went limp without further pressure being applied. In this state, both individuals exhibited the same body position: jaw wide open, dewlap extended, hind legs out, forelegs bent in over the venter. Initially, the individuals were thought to be injured from handling, but when the grip was loosened, the individuals immediately sprung to life and escaped. Both individuals observed were males. Out of seven *A. laeviventris* captured at Finca Haciendo, only the two mentioned above displayed this behavior. A total of nine *A. laeviventris* were collected in Nicaragua with no individuals at other locations displaying the same behavior.

Three days later on 29 May, 2010, at Finca Santa Elena (Boaco Department, Nicaragua), a male *A. cupreus* was captured and displayed the same behavior. Upon feigning death, its body was positioned in exactly the same manner with jaws open, dewlap extended, hind legs out, and forelegs directed inwards across the venter. This incident occurred around 1000 h in broad daylight. This individual was one of three or four captured in the same location at roughly the same time in the same day. A total of 41 *A. cupreus* were collected in Nicaragua from numerous locations, but no other *A. cupreus* captured displayed this behavior.

Presumably, the purpose of tonic immobility is to reduce the likelihood of further attack and thus, contribute to an individual's survival (Imhoff 1982. Proc. West Virginia Acad. Sci. 54:15). It is noteworthy that this behavior was observed during daylight hours in *A. cupreus*, and at night in *A. laeviventris*. Also, *A. cupreus* appears to be significantly more active than *A. laeviventris*. Therefore, this behavior is not limited to slow-moving organisms in the mode of several species of plethodontid, ambystomatid, and salamandrid salamanders (Brodie, Jr. et al. 2004. Herpetologica 30:79–85), nor to those that are more vulnerable in either day or night. It appears that this behavior has developed regardless of those factors. Hennig and Dunlap (1977. Behav. Biol. 20:523–528) reported similar conclusions about diurnal and nocturnal lizards expressing like behaviors, their study focusing on *A. carolinensis* and *Hemidactylus turcicus*. The tonic immobility discussed here regarding Nicaraguan anoles could be a result of predation by birds, which typically capture prey items with their feet instead of their beaks; the pseudo-death of the prey anole could cause a predatory bird to loosen its grip, allowing the lizard to spring to life and escape. Several bird species (especially *Margarops fuscatus* and *Falco sparverius*), are reported as significant predators of Caribbean anoles (McLaughlin and Roughgarden 1989. Ecology 70:617–628). Therefore, the hypothesis that tonic immobility in anoles is a defense mechanism against avian predators may be correct if the anoles in question have similar predators on the mainland. This defense mechanism is unlikely to be successful against predators that typically attack their prey with their mouths and fail to release the prey before mastication and swallowing, including some species of colubrids (Burghardt and Chmura 1993. J. Comp Psychol 107:116–121). It would be interesting to examine these behaviors plus the major predators of anoles in light of their phylogenetic relationships to understand the evolution of defensive behaviors.

The fieldwork where these observations took place was made possible by NSF grant DEB 0949-359. We thank Tom Jenssen, Todd Campbell, Craig Guyer, Jay Savage, Jonathan Losos, and Robert Hoogveld for providing feedback on anole behavior and to Matt Igleski and Emily Oleniczak for assistance in editing and proofreading. We complied with all applicable Animal Care guidelines (CMU-IACUC # 10-02) and all federal and international permits are on file and available from K.E.N.

JOHN G. PHILLIPS (e-mail: phill1jg@cmich.edu) and **KIRSTEN E. NICHOLSON;** Department of Biology, Central Michigan University; Mount Pleasant, Michigan 48858, USA.

***ANOLIS SAGREI* (Brown Anole). DEFENSIVE BEHAVIOR.** Although *Anolis* displays consisting of dewlap extension are typically directed at individuals of the same species, they are occasionally directed at predators. It is difficult to study displays directed at predators, however, because predation is so rarely observed under natural conditions. Most studies describing *Anolis* responses to predators have used captive animals, humans as predators, or a stuffed predator presented as realistically as possible to wild anoles (Leal 1999. Anim. Behav. 58:521–526). Results of such studies are often difficult to interpret because of their artificial nature.

On 28 June 2004 near Lake Buena Vista, Florida, USA, I observed an adult female Boat-tailed Grackle (*Quiscalus major*) on a sidewalk with an *A. sagrei* in its bill. The anole was approximately 7 cm snout–vent length. The bird was vigorously shaking the anole with sideways flicks of its head. After about five seconds, it put the anole down on the pavement. The anole immediately arched its back, fully extended its dewlap, and became immobile. The bird looked at it and did not move for about five seconds. It then pecked the anole several times near the head, which caused the anole to withdraw its dewlap and run. The bird pursued it and picked it up. The anole thrashed in the bird's bill; it did not extend its dewlap. Again, the bird put it down and again it immediately displayed its dewlap. The bird paused for a few seconds, picked up the lizard by its midsection, and flew out of sight.

My observations are inconsistent with predictions of two hypotheses proposed to explain *Anolis* signaling to predators (Leal and Rodriguez-Robles 1997. Anim. Behav. 54:1147–1154). The "flash concealment" hypothesis predicts that an anole will flee immediately after dewlapping, when the predator's attention is most focused on where the dewlap was. The anole I observed, however, extended its dewlap and "froze," not fleeing until it was pecked by the bird. Although it withdrew its dewlap before fleeing, the withdrawal appeared to be a response to pecking rather than a distracting precursor to running. The "pursuit deterrent" hypothesis predicts that the only time an anole will display its dewlap to a predator will be immediately before a potential attack, when it can signal that it has seen the predator and will likely escape if pursued. In the case reported here, the anole had already been captured by the predator.

The observations herein most closely match those of Leal and Rodriguez-Robles (Copeia 1995:155–161), who reported that

A. cristatellus individuals in captivity immediately froze and extended their dewlap after being captured and released by a snake (*Alsophis portoricensis*). This behavior caused the snake to abort or temporarily stop its attack for up to 480 seconds. Leal and Rodriguez-Robles interpreted the display as bluffing—the dewlap presumably made the anole appear larger and more threatening to the snake, thwarting attack. The behavior of the anole during my observations appears to best fit with this interpretation of why *Anolis* species may display their dewlaps to predators, although the bluffing behavior that I observed in *A. sagrei* directed at the grackle was not as effective as it was with a different species of anole and a snake. This leads to further questions regarding whether this bluffing display behavior might be employed by these lizards differently when they are facing different predatory threats (i.e., different species), or may reflect behavioral differences among *Anolis* species.

CATHERINE A. LEVEY, 10264 SW 55th Lane, Gainesville, Florida 32608, USA; e-mail: leveycat@gmail.com.

***ASPIDOSCELIS SACKI* (Sack's Spotted Whiptail). REPRODUCTION.** *Aspidoscelis sacki* is one of the "giant" species of North American whiptail lizards (males to 153 mm SVL; Walker 1981. J. Herpetol. 15:321–328). As presently understood, the geographic range of this species includes parts of the states of Guerrero, Mexico, Morelos, Oaxaca, Puebla, and Veracruz in México (Duellman and Zweifel 1962. Bull. Am. Mus. Nat. Hist. 123:155–210; Valdespino and García-Collazo 2000. Herpetol. Rev. 31:184; Walker and Cordes 1993. Texas J. Sci. 45:187–189). It has one of the largest clutch sizes (mean 5.9, range 3–10 eggs; Walker 1981, *op. cit.*) among species in the genus *Aspidoscelis* (Vitt and Breitenbach 1993. *In* Wright and Vitt [eds.], Biology of Whiptail Lizards [Genus *Cnemidophorus*], pp. 211–243. Oklahoma Museum of Natural History, Norman) based on specimens from Puebla and Oaxaca (Walker, *op. cit.*). However, additional information regarding the reproductive traits of this species is needed from other states in México.

Herein, we report data about clutch size, egg characteristics, and embryonic stage at oviposition of *A. sacki* at Tonatico, State of Mexico (18.75044°N, 99.62025°W; elev. 1597 m). On 1 May 2005 and 10 July 2005, we collected two gravid females, one measuring 125 mm (SVL) with 8 eggs and one measuring 110 mm (SVL) with 5 eggs. Measurements for the eggs of these lizards are: length: mean 18.6 ± 0.37 mm (range 16.7–20.5 mm); width: mean 10.0 ± 0.19 mm (range 8.7–11.1 mm), and total mass: 7.0 g (4.7 g, 9.3 g). Additionally, on 9 June 2010 we collected a gravid female measuring 118 mm (SVL), which oviposited 8 eggs; afterwards it was released. Oviposition took place on 23 June 2010, and the mean egg length was 18.3 ± 0.46 mm (range 17.5–19.2 mm). Both clutch size and egg dimensions for these three lizards were either within or similar to ranges reported for other populations of *A. sacki*, including the months with reproductive activity (Walker, *op. cit.*).

Based on the work of Dufaure and Hubert (1961. Archives Anatomie Microscopie Morphologie Expérimental 50:309–327), the embryonic stage at oviposition of *A. sacki* was 18, which is considerably earlier than stages 21–22 in *A. uniparens* (Billy 1988. J. Zool. 215:55–81; Cuellar 1971. J. Morphol. 133:139–166) and other lizards (Andrews and Mathies 2000. Bioscience 50:227–238; Shine 1983. J. Exp. Zool. 307A:106–112), but may be similar to *A. cozumela* (Manríquez-Morán, unpubl. data).

Individuals of *A. sacki* were collected in the State of Mexico under a scientific collecting permit (FAUT 0186, SEMARNAT), and preserved specimens were deposited in the Centro de Investigación en Recursos Bióticos.

OSWALDO HERNÁNDEZ-GALLEGOS (e-mail: ohg@uaemex.mx), **CARLOS PÉREZ-ALMAZÁN, ANA ESTHELA LÓPEZ-MORENO, GISELA GRANADOS-GONZÁLEZ**, Centro de Investigación en Recursos Bióticos, Facultad de Ciencias, Universidad Autónoma del Estado de México, México, Instituto Literario # 100, 50000, Toluca, Estado de México, México; **JAMES M. WALKER,** Department of Biological Sciences, University of Arkansas, Fayetteville, Arkansas 72701, USA (e-mail: jmwalker@uark.edu).

***CNEMIDOPHORUS ABAETENSIS*. REPRODUCTION.** *Cnemidophorus abaetensis* is endemic to the "Restinga" region from northern Bahia to south of Sergipe, Brazil. This species was only recently described and knowledge of its biology and ecology are lacking (Dias et al. 2002. Copeia 2002[4]:1070–1077; Dias and Rocha 2004. J. Herpetol. 38:586–588; Dias et al. 2005. J. Herpetol. 15:133–137; Dias and Rocha 2007. Braz. J. Biol. 67:41–46). This account presents preliminary data on oviposition and egg characteristics in *C. abaetensis*. On 9 April 2009, a gravid female (SVL = 64.5 mm; weight = 7.5 g) was captured at 0900 h in the Restinga of Abaeté, Salvador, Bahia, Brazil (12.9261°S, 38.3270°W; datum: WGS84; elev. 13 m) in a pitfall trap. The female was transferred to a terrarium (150 x 150 x 50 cm), with seven other individuals (one male and six non-gravid females) of the same species. After three days, two eggs (volume = 603.18 mm^3; measuring accuracy of 0.02 mm) were observed in a nest dug into the substrate, ca. 5 cm deep. Two days later, the eggs hatched. This observation coincides with other studies that show that congeners of this species have low fecundity, with females showing two to four eggs per clutch (Menezes et al. 2004. J. Herpetol. 38:120–122). This species is an active forager and this is a possible explanation for minimal egg production.

IGOR RIOS DO ROSÁRIO, Universidade Católica do Salvador, Salvador, Bahia, Brazil (e-mail: rosario.igor@hotmail.com); **VITOR GOMES SANTA ROSA,** Centro Universitário Jorge Amado, Salvador, Bahia, Brazil (e-mail: v.santa-rosa@hotmail.com); **EDUARDO JOSÉ DOS REIS DIAS,** Laboratório de Biologia e Ecologia de Vertebrados, Departamento de Biociências, Campus Alberto de Carvalho, Universidade Federal de Sergipe, Itabaiana, Sergipe, Brazil (e-mail: ejrdias@hotmail.com).

***CTENOSAURA OEDIRHINA* (Roatán Spiny-tailed Iguana). DIET.** Little is presently known about the ecology of *Ctenosaura oedirhina* (Pasachnik et al. 2010. *In* IUCN 2010. IUCN Red List of Threatened Species. Version 2010.4. <www.iucnredlist.org>). The dietary structure in particular is understudied relative to other members of the genus *Ctenosaura*. During the early part of its life, *C. oedirhina* is assumed to be omnivorous, displaying an ontogenic shift to herbivory when adult. It is of note that most of the known information on the dietary habits of this species comes from observations of captive animals (Köhler 2002. Schwarze Leguane – Freilandbeobachtung, Pflege und Zucht. Offenbach 2. Herpeton, 142 pp.).

Here we present a report on the consumption of the fruit of the Hog Plum (*Spondias mombin*) by an adult male *C. oedirhina* on 14 August 2008 at approx 1300 h at West Bay (16.271414°N, 86.600392°W), Isla de Roatán, Honduras (Fig. 1). Individuals of both sexes and all life stages were observed at this location. To our knowledge this is the first photo-documented account of frugivory in wild *C. oedirhina*, and also the first identification of a specific dietary component for this species.

The fruit of *Spondias mombin* has previously been identified as a dietary component of *C. similis* (Janzen 1985. J. Trop.

FIG. 1. Adult *Ctenosaura oedirhina* consuming a fruit of the Hog Plum (*Spondias mombin*), Isla de Roatán, Honduras.

Ecol. 2:131–155). This species has also been regarded as a dispersal agent of the seeds of other fruiting trees (Traveset 1990. Am. Midl. Nat 123:402–404). Another congener, *C. palearis*, is also a documented frugivore. Its role as a seed disperser of the Organ Pipe Cactus (*Stenocereus pruinosus*) was suggested by Cotí and Ariano-Sánchez (2008. Iguana 3:143–149) who described *C. palearis* as "one of the most important species that feeds on fruits of the cactus *S. pruinosus*."

It is not possible to comment on the significance of *C. oedirhina* as a seed disperser for *Spondias mombin* based solely on the observation described here. A more detailed analysis of the feeding habits of this species is required to substantiate this. Further, it is possible that the consumption of the fruit of *S. mombin* documented here may represent an isolated occurrence, or perhaps a peculiarity of the population at this location. However, given the seed dispersing role of other *Ctenosaura* species and that pollination and seed dispersal by lizards is thought to be most common on islands (Olesen and Valido 2003. TREE 4:177–181), it is possible that *C. oedirhina* may play an important role in seed dispersal for this plant species on the island of Roatán.

ROBERT GANDOLA (e-mail: robertgandola747@hotmail.com) and **CATRIONA HENDRY**, 27 Ayrfield Park, Dublin 13, Dublin, Republic of Ireland.

***CTENOSAURA OEDIRHINA* (Roatan's Spiny-Tailed Iguana). DIET.** Very little is known about the diet of *Ctenosaura oedirhina*. This species is assumed to be primarily herbivorous like other iguanas (Sites et al. 1996. Mol. Biol. Evol. 13:1087–1105; Torres-Carvajal 2007. J. Herpetol. 41:528–531). However, Hendry and Gandola (2011. Herpetol. Rev. 42:274) observed saurophagy within this species, as has been observed in *C. bakeri* (Dirksen and Gutsche 2006. Elaphe 14:51–52) and *C. similis* (Henderson 1973. J. Herpetol. 7:27–33). Here we report on the first case of turtle consumption within this species and, to the best of our knowledge, within Iguaninae.

On 15 May 2010, an individual *Ctenosaura oedirhina* was observed at Gumbalimba Park and Reserve in West Bay, Roatan Island, Islas de la Bahia, Honduras (16.282883°N, 86.595083°W) eating a hatchling *Trachemys venusta uhrigi* (Fig. 1). The same behavior was observed the previous year, during the period of turtle hatching. During our initial observations in 2009, the *Ctenosaura* had already captured the *Trachemys*. Both ctenosaurs had consumed the *Trachemys* within five minutes, headfirst after a period of intense chewing. Given these observations and the saurophagy previously noted, which SAP has also observed multiple times, it seems that this species might be much more omnivorous than previously thought.

***HOLBROOKIA ELEGANS* (Elegant Earless Lizard). PATTERN and REPRODUCTION.** Taxonomy and nomenclature are poorly defined for lesser earless lizards (genus *Holbrookia*) from southeastern Arizona and adjacent New Mexico (Lovich and Jones 2009. *In* Jones and Lovich [eds.], Lizards of the American Southwest, pp. 85–91. Rio Nuevo Publishers, Tucson, Arizona; Jones 2010a. Sonoran Herpetol. 23:170–174). It is important to document natural history traits according to specific localities, so that if a satisfactory taxonomic revision of a species complex is completed, observations may later be attributed to a particular taxon. Lesser earless lizards of semi-desert grasslands and oak woodlands of southeastern Arizona are generally regarded as *H. elegans* (Axtell 2009. *In* Jones and Lovich, *op. cit.*, pp. 150–153). Very little natural history information has been documented for this species, including breeding information (Axtell, *op. cit.*). Here I present an observation of *H. elegans* of different pattern types courting and mating *in situ*. Jones (2010b. Sonoran Herpetol. 23:174–177) discussed the pattern types of *H. elegans*, noting that a patternless morph is found in several populations.

On 11 June 2010, I observed a patternless male *H. elegans* court and copulate with a typically patterned female at Kartchner Caverns State Park, Cochise Co., Arizona, USA. For the duration of the observation (30 min. [1715–1745 h]), the male and female stayed within about 0.5 m of each other. The female generally remained motionless on the surface of the ground, while the male was more active. During courtship, the male did frequent pushup displays, usually from atop small rocks. Most of the displays were "slow," as in territorial displays, including the extension of the dewlap. After a series of slow displays, the male exhibited a "rapid" display of head bobs. After the rapid display, the male would leave the rock and circle the female, possibly doing more displays, then return to a rock, or caress the female with his snout or front foot. The hind leg and tail sometimes touched the female during the caressing phase. The female remained

motionless during the courtship. Then the male would go back to a rock (usually the same cobble-sized rock) and repeat the process. Only on one occasion during my observation did the caressing advance to copulation. During copulation, the male bit the female on the loose skin of the right side of the neck. He then inserted his right hemipenis into the left side of the female's cloaca. The courtship and copulation were consistent with the stereotypical behavior of most other iguanids and phrynosomatids (Carptenter 1967. *In* Milstead [ed.], Lizard Ecology: A Symposium, pp. 87–105, Univ. Missouri Press, Columbia). When I returned the following day, the male and female (presumably the same pair) were still in the vicinity, but no additional mating behavior was observed.

Visual cues play a role in mate selection, mating success, or mate rejection; this has been the topic of several studies in other species of *Holbrookia* (e.g., Cooper 1991. Amphibia-Reptilia 12:57–66; Hager 2001. J. Herpetol. 35:624–632; Robertson and Rosenblum 2009. Biol. J. Linn. Soc. 98:243–255; Rosenblum 2008. J. Herpetol. 42:572–583). Even though some individual *H. elegans* in a population lack a dorsal pattern, they still exhibit the visual cue coloration necessary for social signaling; males possess black dorsolateral bars with blue areolae and often an orange-red throat spot, and females retain a distinctive red-orange throat spot and take on the orange and yellow lateral nuptial coloration signifying that they are gravid (Axtell, *op. cit.*; Jones 2010b, *op. cit.*). Thus, there is no evidence that patternless individuals are selected against for mating, presumably because they retain the social signaling coloration. This makes sense because the phenotype is currently present within several populations. This would ensure that the genes responsible for the lack of a pattern can remain in a population, as the plain dorsum may be selected for its cryptic benefits within an environment with a plain background (e.g. dunes, as is seen in *H. maculata ruthveni*) (Robertson and Rosenblum, *op. cit.*; Rosenblum, *op. cit.*).

***IBEROLACERTA MONTICOLA* (Cantabrian Rock Lizard). LONGEVITY.** Maximum longevity in natural populations can be determined directly, by monitoring marked individuals, or indirectly, using methods such as skeletochronology. By using this latter method, the maximum age of *Iberolacerta aurelioi* was estimated at 14 years (females) and 16 years (males) (Arribas 2004. Herpetozoa 17:3–18; Arribas 2007. Istoria Naturau e Evolucion dera Cernalha Aranesa, *Iberolacerta aranica*. Consell Generau d'Aran, Huesca. 446 pp.), these being among the oldest known longevity estimates for a small-sized lacertid lizard. In *Iberolacerta monticola*, another endemic lacertid species of the Iberian Peninsula, a maximum longevity of 10 years was estimated via skeletochronology from a Portuguese population (Moreira et al. 1999. Bases para a Conservaçao da Lagartixa-da-montanha [*Lacerta monticola*]. Estudos de Biologia e Conservaçao da Natureza 25, Lisboa, 68 pp.). By tracking marked individuals, the maximum life span of the same species was determined to be 12 years in a population in northwestern Spain (Galán et al. 2007. Munibe 25:34–43). For other species of this genus, including seven species endemic to the Iberian Peninsula and one of the Balkans, maximum longevity is unknown.

Since the early 1990s I have been monitoring a population of *Iberolacerta monticola* in the Lambre River Valley (municipality of Vilarmaior, A Coruña province, northwestern Spain, 43.3172°N, 8.1396°W, datum: WGS 84; 40 m elev.) and have been able to calculate the maximum life span of some individuals by marking. This population lives in the walls of a hydroelectric plant, occupying a small area (Galán et al., *op. cit.*).

One male was marked as a subadult in 1995 (at one year of age). This individual was recaptured every year from 1995 until 2008, when it disappeared at age 14. At that time it measured 77 mm (SVL). Another male was marked upon hatching, in 1995, and was recaptured every year thereafter. The individual is still alive at the time of this writing (2010) at 15 years of age and measuring 76 mm (SVL). This longevity, however, does not appear to be common, as other males (ages based on mark-recapture data) of the same population have disappeared (and presumably died) at younger ages: two at six years of age, one at seven, two at eight, and one at nine years of age. All had large body sizes (SVL > 73 mm) at the time of last observation. Recapture rates of females were much lower, thus, sufficient data pertaining to most female maximum longevity were not obtained. Only the age and the year of disappearance (presumably death) are known for four females: one at five years of age, two at six years of age, and one at eight years of age.

This maximum longevity is of interest for a relatively small lacertid living at low altitudes (nearly sea level), with very long periods of annual activity (nine months; February–October). *Iberolacerta aurelioi*, which reaches a similar longevity (14–16 years) and is also small, lives in the high mountains (at altitudes of 2100–2900 m), where the annual activity period is only four months (May–August). This limits their annual body growth and for this reason, the acquisition of sexual maturity is delayed for several years, which contributes, among other factors, to increased longevity (Arribas, *op. cit.*). Species of small lacertid lizards with high annual growth rates living at low altitudes reach sexual maturity earlier, so their longevity is relatively shorter (Galán 1999. J. Zool., Lond. 249:203–218). There is a negative correlation between the duration of annual activity and longevity, indicating that the species living at higher altitudes has greater longevity. Therefore, in this population of *I. monticola* at Lambre, living at low altitude, a lower maximum longevity would be expected.

The study population also has a relatively high number of predators, ranging from saurophagus snakes, such as *Coronella austriaca*, to mammalian carnivores, such as *Genetta genetta* and *Felis catus* (Galán, unpubl. data). It is possible that other factors involved in the life history of this species might be responsible for the high longevity of some individuals.

PEDRO GALÁN, Departamento de Bioloxía Animal, Bioloxía Vexetal e Ecoloxía, Facultade de Ciencias, Universidade da Coruña, Campus da Zapateira, s/n, 15071–A Coruña, Spain; e-mail: pgalan@udc.es.

***IGUANA IGUANA* (Green Iguana). PREDATION.** *Iguana iguana* is an established, nonnative species in southern Florida (Krysko et al. 2007. Iguana 14[3]:2–11) that often lives in vegetation along the edges of bodies of water inhabited by the American Alligator (*Alligator mississippiensis*). Kern (2004. Dealing with iguanas in the South Florida landscape. Univ. Florida IFAS Fact Sheet ENY-714) claimed that *A. mississippiensis* may occasionally prey upon adult *I. iguana* in the water, but such predation has not been documented in the literature. In Central and South America, at least four crocodilian species have been reported preying upon *I. iguana* (Antonio Rivas et al. 1998. Herpetol. Rev. 29:238–239; Dugan et al. 1981. J. Herpetol. 15:409–414; Platt et al. 2006. Herpetol. J. 16:281–290). Here, we report a feeding attempt by an *A. mississippiensis* on an adult *I. iguana*.

PHOTO BY MICHAEL COHEN

FIG. 1. *Alligator mississisippiensis* with an adult male *Iguana iguana* in its mouth at Wakodahatchee Wetlands, Palm Beach Co., Florida, USA, 31 December 2010.

At 1149 h (EST) on 31 December 2010, one of us (MJC) observed an *A. mississippiensis* (ca. 2 m TL) with the head of an adult male *I. iguana* in its mouth (Fig. 1) at Wakodahatchee Wetlands, Delray Beach, Palm Beach Co., Florida, USA (26.4778°N, 80.1419°W, WGS 84; 5.5 m elev.). During the ca. 30 min of observation, the *A. mississippiensis* thrashed vigorously for ca. 30 sec, attempting unsuccessfully to dismember the carcass, which appeared fresh. When last observed, the *A. mississippiensis* had crawled onto land with the head of the *I. iguana* still in its mouth. The air temperature was ca. 25°C.

MICHAEL J. COHEN, 3265 NE 31st Avenue, Lighthouse Point, Florida 33064, USA (e-mail: mjcpa@bellsouth.net); **KEVIN M. ENGE**, Florida Fish and Wildlife Conservation Commission, 1105 SW Williston Road, Gainesville, Florida 32601, USA (e-mail: kevin.enge@myfwc.com).

***LIOLAEMUS CHACOENSIS* (Chaco Tree Iguana). CLUTCH SIZE.** *Liolaemus chacoensis* is an inhabitant of the arid chaco phytogeographical province (Cei 1993. Reptiles del Noroeste, Nordeste y Este de la Argentina. Mus. Reg. Sci. Nat. Torino Monogr. 14:1–949). The biology of this species is poorly known. In this note we report the clutch size for one lizard under laboratory conditions in order to contribute to the limited knowledge of this species' reproductive biology.

During January 2011, a female *L. chacoensis* (46.8 mm SVL, 3.3 g) was observed basking and was then hand-captured in the field at 1230 h in San Juan province, Valle Fértil Department, in La Mesada Creek (31.02377°S, 67.29694°W; datum: WGS 84; elev. 899 m). Six days post capture, on 1 February 2011, this female deposited three eggs in the laboratory, at an ambient air temperature of 25°C and 30% relative humidity. Total mass of the eggs was 0.9 g, equal to 27.2% of the lizard's mass (post laying). Mean egg length was 11.6 ± 0.65 mm and mean egg width was 6.3 ± 0.45 mm. Mean egg volume was also estimated (43.3 ± 3.03 mm^3) using the equation [$V = 4/3\ (L/2)\ (W/2)^2$] for an elliptical sphere (Dunham 1983. *In* Huey et al. [eds.], Lizard Ecology, pp. 261–280. Harvard University Press, London.).

EDUARDO A. SANABRIA (e-mail: sanabria.eduardoa@gmail.com), **LORENA QUIROGA, GUILLERMINA GALVANI, PABLO PASTOR, MARIO HERRERA, ANA NAVAS, DANIELA MORENO, ARIEL CATALDO,** Departamento de Biología, Universidad Nacional de San Juan, Argentina.

***PHOXOPHRYS NIGRILABRIS* (Black-lipped Eyebrow Lizard). REPRODUCTION.** *Phoxophrys nigrilabris* is restricted to Borneo (Manthey and Grossmann 1997. Amphibien & Reptilien Südostasiens. Natur und Tier – Verlag, Münster, Germany. 512 pp.). Information on reproduction of *P. nigrilabris* is limited to a report that it may occur around the middle of the year (Das 2006. A Photographic Guide to Snakes & Other Reptiles of Borneo. Ralph Curtis Publ., Sanibel Island, Florida. 144 pp.). The purpose of this note is to provide additional information on reproduction of *P. nigrilabris*.

A sample of 11 *P. nigrilabris* (ten males: mean SVL = 45.2 mm ± 6.4 SD, range = 31–53 mm and one female, SVL = 55 mm) from Sarawak, Borneo was examined from the herpetology collection of the Field Museum of Natural History (FMNH), Chicago, Illinois: Kapit Division FMNH 138477, 138483, 138485, 145673, 145676, 145677; Bintulu Division FMNH 147656, 148986, 195479, 269084, 273325. Lizards were collected 1962–1964, 1970, 2005, 2007. For histological examination, the left testis was removed to identify the stage of the testicular cycle in each male. The testes were embedded in paraffin, sections cut at 5µm using a rotary microtome and slides were stained with hematoxylin followed by eosin counterstain. Histology slides are deposited in FMNH. Males in the following monthly samples were undergoing spermiogenesis in which the lumina of the seminiferous tubules were lined by sperm or groups of metamorphosing spermatids: January (N = 2), February (N = 1), May (N = 2), July (N = 1), September (N = 1), October (N = 1). The smallest male to exhibit spermiogenesis measured 42 mm SVL (FMNH 195479). Two males (31 and 40 mm SVL) exhibited testicular recrudescence in which spermatocytes predominated; no sperm were present. These (FMNH 147656, 273325) were classified as subadults. One female (FMNH 145673) from March contained two yolking follicles (> 3 mm diameter) indicating a clutch of two eggs would be produced. The above suggests *P. nigrilabris* males exhibit an extended period of reproduction as has been reported for other species of agamid lizards (*Draco*) from Borneo (Inger and Greenberg 1966. Ecology 47:1007–1021).

I thank Alan Resetar (FMNH) for permission to examine *Phoxophrys nigrilabris*.

STEPHEN R. GOLDBERG, Department of Biology, Whittier College, Whittier, California 90608, USA; e-mail: sgoldberg@whittier.edu.

***PLESTIODON SUMICHRASTI* (Sumichrast's Skink). PREDATION.** There are many reports of large tropical spiders preying upon amphibians and reptiles (e.g., Antônio de Freitas et al. 2010. Herpetol. Rev. 41:202; Brito De-Carvalho et al. Herpetol. Rev. 2010. 41:336–337; Cicchi et al. 2010. Herpetol. Rev. 41:207; Hamidy et al. 2010. Herpetol. Rev. 41:66–67). Although many of these reports document predation on small frogs and lizards (< 4 cm SVL), larger prey items are occasionally taken or attempted (e.g., Silva Siqueira Nunes et al. 2010. Herpetol. Rev. 41:367–368). Here we report an instance of a relatively large lizard as a prey item for a tarantula from the highlands of southeastern Guatemala.

On 2 October 2010 we were conducting a herpetofaunal survey in the Sierra Caral of Izabal, Guatemala. At approximately 1800 h while pulling apart a large fallen tree trunk, we discovered a cavity that contained a partially digested juvenile *Plestiodon sumichrasti* (ca. 6 cm SVL; Fig. 1 [top]). Further excavation immediately behind the partially digested lizard revealed a large male tarantula referable to the genus *Brachypelma* (Fig. 1 [bottom]). This observation occurred near Cerro Pozo de Agua at about 850 m (15.39367°N, 088.69183°W; WGS84 datum). The slightly dissolved skink was collected and deposited in the natural history

COLOR REPRODUCTIONS SUPPORTED BY THE THOMAS BEAUVAIS FUND

FIG. 1. Predation of *Plestiodon sumichrasti* (top) by *Brachypelma* sp. (bottom) in the Sierra Caral of Izabal, Guatemala.

collections of the Museo de Historia Natural of the Universidad de San Carlos in Guatemala City (USAC 2738; Field ID: CRVA 2162).

We thank Mónica Barrientos, Obdulio Javier Villagran, Eric N. Smith, and FUNDAECO for field and logistical assistance. Chris A. Hamilton and his colleagues kindly helped with tarantula identification. This observation was made while conducting field work supported by Conservation International. Scientific collecting permits were issued by Consejo Nacional de Areas Protegidas ([CONAP]; 030/2010 to E. N. Smith, and 008/2010, 12809 to C. R. Vásquez-Almazán).

JEFFREY W. VÁSQUEZ-ALMAZÁN** (e-mail: crvasal@yahoo.com.mx), Museo de Historia Natural, Escuela de Biología, Universidad de San Carlos, Ciudad de Guatemala, Guatemala.

***POLYCHRUS MARMORATUS* (Common Monkey Lizard; Bicho-preguiça). PREDATION.** *Polychrus marmoratus* is an arboreal lizard associated with forested habitats, occurring in northern South America east of the Andes in Amazônia and in the Atlantic Rainforest, from Recife, in Pernambuco state, to north of São Paulo state (Ávila-Pires 1995. Zool. Verh. Leiden 299:1–708). This lizard is known to be preyed upon by birds (Beebe 1944. Zoologica 29:195–216; Test et al. 1966. Misc. Publ. Mus. Zool. Univ. Michigan 128:1–63) and snakes (Cunha and Nascimento 1994. Bol. Mus. Par. Emílio Goeldi, Zool. 9:1–191). Herein, we make the first report of saurophagy for the Crested Capuchin Monkey (*Cebus robustus*) on *P. marmoratus*.

On 11 March 2010, at 1130 h, one of us (WPM) observed two adult Crested Capuchin Monkeys in the canopy of an area of reforestation at Reserva Natural Vale (RNV), Linhares municipality, Espírito Santo state, southeastern Brazil (19.153611°S, 40.039722°W; datum WGS84, elev. ca. 60 m), while studying the ecology and behavior of these monkeys. One of the capuchins had a lizard (*Polychrus marmoratus*) in its hand and ate parts of it (i.e., head, tail, thighs, and some lateral parts). The other Crested Capuchin assumed a position of submission, as if "begging" for a piece of the prey. After six minutes of observation, the individual that had consumed parts of the lizard then discarded it, whereupon it fell to the ground. This action did not appear to elicit any interest from the other monkey. On the same date at 1512 h, a juvenile Crested Capuchin (also in the same reforestation area) was observed with a lizard in his hand. The capuchin ate the tail and lateral parts of the animal and was furthest from the group without other monkeys around. After four minutes, it threw the animal to the ground. The remains were identified as the lizard *Polychrus marmoratus* (Fig. 1).

Cebus robustus is a poorly known, endangered species endemic to the Atlantic coastal forest from the Rio Jequitinhonha in southern Bahia state, through northern Espírito Santo and the Rio Doce in Minas Gerais state, Brazil (Martins 2005. Distribuição Geográfica e Conservação do Macaco-prego-de-cristas [*Cebus robustus*] em Minas Gerais, Brasil. Universidade Federal de Minas Gerais. Msc dissertation; unpubl. data). This finding suggests that *C. robustus* is an opportunistic, generalist predator, as is known for most species of this genus (Fragaszy et al. 1990.

PHOTO BY WPM

FIG. 1. The remains of the *Polychrus marmoratus* immediately after being partially eaten by *Cebus robustus* and dropped to the ground.

Folia Primatol. 54:114–118). Observations on the ecology of this monkey are needed and records for vertebrates in its diet are rare in the literature.

We are indebted to the Companhia Vale for support and allowing one of us (WPM) access to lodging facilities and the reserve. WPM was supported by grants from the Brazilian science council (CNPq), Primate Conservation Inc., Primate Action Fund (Conservation International/Margot Marsh Biodiversity foundation), and U.S. Fish Wildlife Service. JC was funded by Fundação de Amparo à Pesquisa do Estado de São Paulo (FAPESP). We thank Jackson Shedd for helpful comments on this manuscript.

***PTYODACTYLUS GUTTATUS* (Sinai Fan-fingered Gecko). REPRODUCTION.** *Ptyodactylus guttatus* ranges from northeastern Egypt, north to southern Syria, and east to Jordan where it inhabits mountainous and hilly country (Baha El Din 2006. A Guide to the Reptiles and Amphibians of Egypt. The American University in Cairo Press, Cairo. 359 pp.). *Ptyodactylus guttatus* has been reported to produce multiple clutches of one to two eggs in summer and utilize communal laying sites (Bouskila and Amitai 2001. Handbook of Amphibians & Reptiles of Israel. Keter Publishing House, Jerusalem. 345 pp.; Johnston and Bouskila 2007. J. Herpetol. 41:506–513; Werner 1985. *In* Rocek [ed.], Studies in Herpetology, Proceedings of the European Herpetological Meeting [3rd Ordinary General Meeting of the Societas Europaea Herpetologica], pp. 141–144. Prague). Breeding occurs mainly in spring and early summer (Disi et al. 2001. Amphibians and Reptiles of the Hashemite Kingdom of Jordan. An Atlas and Field Guide. Edition Chimaira, Frankfurt am Main. 408 pp.). The purpose of this note is to present additional information on the timing of the reproductive cycle of *P. guttatus*.

A sample of 28 *P. guttatus* consisting of eleven male (mean SVL = 71.1 mm ± 8.0 SD, range = 54–79 mm) and seventeen females (mean SVL = 70.3 mm ± 6.0 SD, range = 60–80 mm) from Israel were examined from the Zoology Museum of Tel-Aviv University (TAUM), Tel-Aviv, Israel. Lizards were collected 1958 to 1990. Lizards examined by District were: Central: 10137, 13576, 13629, 13866, 13869, 14034, 14035, 14144, 15604; Haifa: 10536; Jerusalem: 13573; Jordan Valley: 8535, 13196, 14036; Southern: 3041, 4226, 4228-4232, 4457, 4458, 4460–4462, 11116, 14032.

For histological examination, the left gonad was removed to check for yolk deposition or corpora lutea in females and to identify the stage of the testicular cycle in males. Counts were made of enlarged ovarian follicles (> 4 mm length) or oviductal eggs. Tissues were embedded in paraffin, sectioned at 5µm and stained with hematoxylin followed by eosin counterstain. Histology slides are deposited in TAUM.

Two stages were noted in the testicular cycle; (1) recrudescence in which there is a proliferation of spermatocytes for the next period of spermiogenesis (sperm formation) and (2) spermiogenesis in which lumina of the seminiferous tubules are lined by sperm or clusters of metamorphosing spermatids. Monthly samples were: March (N = 5) three in recrudescence, two in spermiogenesis; June (N = 1) spermiogenesis; October (N = 2) spermiogenesis; November (N = 3) two in recrudescence, one in spermiogenesis. The smallest reproductively active male (spermiogenesis in progress) measured 62 mm SVL and was collected in October (TAUM 13629). One male in recrudescence from March (TAUM 4461) measured 54 mm SVL and was considered a sub-adult.

Four stages were noted in the ovarian cycle: (1) quiescent, no yolk deposition observed; (2) corpus luteum from a previous ovulation; (3) enlarged ovarian follicles (> 4 mm); (4) oviductal eggs. Monthly samples were: February (N = 1) corpus luteum; April (N = 1) quiescent; May (N = 3) one quiescent, two with enlarged ovarian follicles; July (N = 1) quiescent; September (N = 1) quiescent; October (N = 6) five quiescent, one oviductal; November (N = 4) quiescent. Mean clutch size for three females was 2.0. The smallest reproductively active female (two enlarged follicles > 4 mm length) measured 65 mm SVL and was collected in May (TAUM 8535).

My data indicate that *P. guttatus* exhibits reproductive activity in both spring and autumn as some males were undergoing spermiogenesis in March, June, and October, November and females from May and October exhibited reproductive activity. One female from February contained a corpus luteum, which was likely from an autumn ovulation.

I thank Shai Mari (TAUM) for permission to examine *P. guttatus* and Erez Maza (TAUM) for processing the loan.

***SCELOPORUS POINSETTII* (Crevice Spiny Lizard). ECTOPARASITES.** Ectoparasitism from mites of the genus *Eutrombicula* (Trombiculidae) is a common infestation on many vertebrate species (Brennan and Reed 1974. J. Parasitol. 60:699–711; Vercammen-Grandjean and Audy 1965. Acarologia Suppl. 7:280–294). However, little is known about the actual frequency of parasitic loads, how loads fluctuate in dissimilar environmental conditions, how long parasites infest their hosts (Goldberg and Bursey 1993. J. Wildl. 29:142–144), and how parasitic loads vary among individuals (sexes and life stages) in the same geographic area (Klukowski 2004. J. Herpetol. 38:141–144). We herein report changes in mite infestation on one adult male *S. poinsettii* before and after periods of significant rainfall on Indio Mountains Research Station (IMRS) located in the Trans-Pecos region of the Chihuahuan Desert, ca. 40 km SW of Van Horn, Texas, USA. Rainfall and temperature readings were recorded by a HOBO weather station located in close proximity to the event reported below.

On 11 September 2010, an adult male *S. poinsettii* (106 mm SVL; 42.2 g) was captured at 1130 h on a rocky outcrop (Fig. 1) located ca. 2.0 km N of the IMRS headquarters complex (30.79438°N, 105.01407°W, WGS84; 1268 m elev.); the area surrounding the outcrop was covered by typical Chihuahuan Desert scrub vegetation. The average ambient temperature for that day was 25.3°C. The lizard was immediately placed into a plastic zip-lock bag and quickly taken to the IMRS laboratory for processing. We measured and weighed the lizard and used a stereoscopic dissecting microscope to count the number of mites present on its body. The lizard had an infestation of immature mites (*Eutrombicula* sp.) under its cervical folds on each side of the neck; none was observed elsewhere on the body and none had fallen off into the plastic bag during the short transport time. We observed a total of 33 mites; 17 under left cervical fold and 16 under the right fold. Cervical folds seemed to be ideal places for

mites to invade because non-scaled skin is exposed inside the structure, and the fold itself provides partial shade from solar radiation. Also, this was one of the highest loads of mites observed among multiple species of lizards occurring on IMRS during prior mark-recapture studies. When finished, we marked the lizard with toe-clips and then released it a short time later back on the same outcrop.

Two weeks later, on 25 September 2010, we recaptured the same lizard on the same rock at ca. 1200 h. The lizard was placed into another zip-lock plastic bag and quickly taken to the laboratory for processing. The lizard gained 1.6 g during the two-week period (SVL was the same), but the mite infestation appeared much heavier than before. After carefully counting them several times, 79 mites were documented and again, they were only under the cervical folds. This time, the *S. poinsettii* had 51 mites under the left cervical fold, and 28 mites under the right fold. The parasite load increased 3x on the left side while increasing 1.75x on the right side. The overall increase in the ectoparasitic load was roughly 2.4x from that observed on 11 September.

The increase in abundance of mites could be attributed to different factors. However, in this case, due to the brief two-week period between the two captures, it is reasoned that rainfall, and possibly decreased temperature, influenced increasing mite infestation. Within that time period, two significant rain events occurred in the area. On 19 September 2010, eight days after initial capture and release, it rained 3 mm and the 24 h period had an average temperature of 21.6°C. Two days later, on 21 September 2010, it rained 9.15 mm and the average temperature for the day was 24.3°C. Thus, increased water availability, in possible combination with lower ambient temperatures, likely played a role increasing mite infestation on the lizard, a conclusion partially supported by another study investigating a similar situation. Phang and Manikumaran (1977. Southeast Asian J. Trop. Med. Publ. Health 8:217–20.) found a greater abundance of trombiculid mite larvae along transects during heavy rainfall events when comparing increased rainfall to periods of dryness, but they were hard to impossible to find during dry periods. They also exposed larval mites to simulated rainfall, which retained mite larval populations for longer periods during dry weather. Temperature and dryness were not determined to be a contributor to the frequency changes observed in the parasitic load, because they thought that the amount of time required for those factors to take effect on physiology and immunity processes was too short. We tentatively associate the load frequency changes on the *S. poinsettii* to environmental factors, especially rainfall, primarily because the lizard was caught during a brief two-week period when rainfall events occurred. Significant rainfall probably concentrates these larval mites in dry microhabitats, where they can be picked up by the lizards occurring in the areaby.

JOHNSON** (e-mail: jjohnson@utep.edu), **VICENTE MATA-SILVA, ARTURO ROCHA,** and **ROSS COUVILLON,** Department of Biological Sciences, The University of Texas at El Paso, El Paso, Texas 79968, USA; **FERNANDA DE LA CERDA,** Department of Environmental Sciences, The University of Texas at El Paso, El Paso, Texas 79968, USA.

***TROPIDURUS HISPIDUS* (Peters' Lava Lizard). PREDATION.** Predator-prey relationships play an important role in community structure (Miller et al. 2006. J. Anim. Ecol. 75:101–110), however, predation events in nature are often difficult to quantify due to the rarity of observations (Shepard 2007. Herpetologica 63:193–202). Birds are potential predators of small vertebrates including rodents (Motta-Junior and Talamoni 1996. Ararajuba 4:38–41), anurans (Toledo et al. 2004. Herpetol. Bull. 94:31–32), and lizards (França and Braz 2009. Biotemas 22:243–245). Lizards are commonly recognized prey items of birds in Neotropical habitats (Rocha and Vcbradic 1998. Ciência e Cultura 50:364–368).

PHOTO BY C. B. DE-CARVALHO

COLOR REPRODUCTIONS SUPPORTED BY THE THOMAS BEAUVAIS FUND

FIG. 1. *Rupornis magnirostris*, preying on an adult *Tropidurus hispidus*, Sergipe, Brazil.

On 18 October 2010 at 1002 h in retinga of Aruana Beach, south coast of Aracaju, Sergipe, Brazil (11.0122°S, 37.0650°W, 5 m elev., datum SAD69), we observed a Roadside Hawk (*Rupornis magnirostris*) preying on an adult *Tropidurus hispidus* (Fig. 1). The hawk was near its nest, in which we observed a chick. It is possible the prey was to feed the chick we but did not observe any interactions. The Roadside Hawk has a diet of reptiles, amphibians, insects, mammals, and birds (Panasci and Whitacre 2002. Wilson Bull. 114:114–121). Predation on lizards by birds have been reported for Brazil (França and Braz 2009, *op. cit.*; Sherpard 2007, *op. cit.*), however, this is the first record for the restinga area in the northeast.

SQUAMATA — SNAKES

***BOIGA IRREGULARIS* (Brown Treesnake). PREDATION ATTEMPT BY CRAB.** The Coconut Crab (*Birgus latro*), also known as the Robber Crab, is the heaviest terrestrial invertebrate in the world with a mass occasionally exceeding 3 kg (Amesbury 1980. Univ. Guam Tech. Rep. 17:1–39). While primarily an omnivore

feeding on vegetative matter and scavenging for dead animals, it may also prey on live invertebrates and vertebrates such as sea turtle hatchlings and rats (Greenaway 2003. Mem. Mus. Victoria 60:13–26; Kessler 2005. Crustaceana 78:761–762).

On 8 March 2010 we were searching for snakes in northern Guam. At 2230 h we observed a Coconut Crab sitting at the entrance to a tree (*Premna obtusifolia*) hole ca. 0.7 m above ground, holding onto the tail of an adult *Boiga irregularis* with one of its claws. The snake was partly suspended in mid-air and had anchored the forepart of its body to some roots and branches close to the ground, apparently trying to pull loose. As we approached, the crab retreated into the tree hole while maintaining its hold of the snake's tail. A few minutes later, after more human disturbance, the crab released the snake. The crab had a thoracic width of about 45–50 mm, which would correspond to a thoracic length of about 22–25 mm (unpubl. data) and a mass of about 100 g (Amesbury, *op. cit.*). We captured the snake and determined that it was a gravid female (SVL = 1124 mm; total length = 1423 mm; 255 g). Close inspection of the tail revealed minor indentations from the crab's claw, but there was no bleeding, nor any visible rupture of the skin.

There have been several observations of both terrestrial and marine crabs feeding on snakes (Maitland 2003. J. Crustacean Biol. 23:241–246; Voris and Jeffries 1995. J. Tropical Ecol. 11:569–576) but most accounts deal with snakes smaller than the one we observed. It is possible that the crab eventually would have started feeding on the tail while it was still attached to the snake, even if it had failed to kill the snake (Maitland, *op. cit.*).

Of the 295 individual *Boiga irregularis* we have encountered and marked in our main study population to date, 15% suffered damage to the tail. Damage ranged from the tip to most of the tail lost, leaving only a short stump. In 21 cases the damage had occurred before we first encountered a snake, so we do not know the size of the snake at the time of the injury. But for 23 snakes that we captured before and after tail damage (including major and minor damage), the mean of the snakes' pre- and post injury sizes is 1095 mm SVL. Some of these tail damages might have been inflicted by coconut crabs (or possibly other terrestrial crabs, several smaller species of which inhabit the area) in attacks similar to the one we observed. The Orote Peninsula in Guam reputedly has high densities of crabs (*B. latro* and others) and 40% of the *Boiga irregularis* there have damaged tails (Deni Porej, pers. comm.), suggesting a correlation between crab densities and incidence of tail damage.

Among snakes in our study population, we have seen tail damage in only five snakes < 800 mm SVL, and in two of these, only the very tip of the tail was missing. However, crab attacks on small juvenile snakes are likely to end in death for the snake, hindering our ability to assess rates of attack and the effects of such predation attempts on snake fitness. Even so, careful analyses of size-dependent injury incidences may help reveal potential impact of predators on prey populations when direct observations of predatory attempts are lacking.

BJORN LARDNER (e-mail: Bjorn.Lardner@ColoState.edu) and **JULIE A. REED** and **GORDON H. RODDA,** U.S. Geological Survey, Fort Collins Science Center, 2150 Centre Avenue, Building C, Fort Collins, Colorado 80526-8118, USA.

***BOIGA IRREGULARIS* (Brown Treesnake). PREDATION ATTEMPT BY PRAYING MANTIS.** The Western Pacific island of Guam is known for its introduced population of *Boiga irregularis* that has had considerable negative effects on vertebrates native to the island (Rodda et al. 1997. BioScience 47:565–574; Savidge 1987. Ecology 68:660–668). Few animals in Guam are known to prey on the snakes, but Mangrove Monitors (*Varanus indicus*) and feral/domestic cats (*Felis catus*) may do so (Fritts and Rodda 1998. Annu. Rev. Ecol. Sys. 29:113–140; pers. obs.).

In Guam, on the evening of 11 November 2009, the first author was filming a small (SVL = 450–500 mm) *B. irregularis*, perched in vegetation 4 m above ground. The snake suddenly started thrashing violently and after about ten seconds it fell to the ground. The snake slithered through a meter of grass and coiled up under a flattened soda can. A praying mantis was observed next to where the snake first landed on the ground. A review of the video footage (http://vimeo.com/13407786) showed that the snake had been attacked by a large praying mantis (*Hierodula patellifera*) that held the snake's head with both forelegs. The mantis tried to hold on to the vegetation, but the snake eventually pulled the mantis from its perch and both fell to the ground. The snake was not closely examined after the event, but it did not appear to be harmed.

Mantids have been observed preying on birds, lizards, frogs, and mice (Benrekaa and Doumandji 1997. Entomologiste 53:253–256; Brothers 2008. Herpetol. Rev. 39:351; Nickle 1981. Proc. Entomol. Soc. Washington 83:801–802; Ridpath 1977. J. Aust. Entomol. Soc. 16:153–154). Our observation suggests that juvenile *B. irregularis* might also be at risk of mantid predation, as mantids have been observed to kill large prey even in situations where they are dragged around by the prey item (Reitze and Nentwig 1991. Oecologia 86:568–574).

In Guam, hatchling *B. irregularis* measure 290 mm SVL (Lardner et al. 2009. Herpetol. Cons. Biol. 4:313–323) to 430 mm SVL (Rodda et al. 1999. *In* Rodda et al. [eds.], Problem Snake Management: the Habu and the Brown Treesnake, pp. 44–80. Cornell University Press, Ithaca, New York). Average-sized hatchlings (SVL = 360 mm) typically weigh 7–8 g, but we have seen a *B. irregularis* that weighed merely 4 g. Assuming the snake observed measured 475 mm SVL, its weight would have been ca 15 g. Adult specimens of *H. patellifera* collected from the site where the predation attempt occurred have a mean head-body length of 69 mm and an average mass of 2.9 g (range 1.6–4.1 g; N = 6). Thus, the snake that was attacked probably weighed about five times as much as the praying mantis, but some hatchling *B. irregularis* weigh no more than a large *H. patellifera*. For a comparison, the large mantid *H. werneri* has been seen feeding on frogs and birds weighing as much as three times the mantid's weight (Ridpath, *op. cit.*).

Hierodula patellifera are common in trees and bushes frequented by small *B. irregularis* on Guam. It therefore seems plausible that encounters between small snakes and large mantids are not rare. Further information about the frequency and outcomes of such encounters, especially encounters that lead to death or serious injury for the snake, would be useful.

We thank Aubrey Moore for help with mantid identification and references. Any use of trade, product, or firm names is for descriptive purposes only and does not imply endorsement by the U.S. Government.

***BOTHROPS LEUCURUS* (Bahia Lancehead). CAUDAL LURING.** Caudal luring, the wriggling movements of a conspicuous tail tip made by an otherwise cryptically colored snake in the presence of potential prey, has been reported for several species of Boidae, Viperidae, and Elapidae (Sazima 1993. Copeia 1993:222–226). *Bothrops leucurus* is a terrestrial and nocturnal snake from the Atlantic Forest Domain of northeastern and eastern Brazil (Campbell and Lamar 2004. The Venomous Reptiles of the Western Hemisphere. Cornell Univ. Press, Ithaca, New York. 870 pp.). It is a generalist species that preys on amphibians, lizards, and rodents (Freitas 1999. Serpentes da Bahia e do Brasil. Ed DALL, Feira de Santana, Bahia. 80 pp.; Freitas 2003. Serpentes Brasileiras. Malha-de-Sapo-Publicações, Lauro de Freitas, Bahia. 160 pp.). We observed tail displays in three juvenile *B. leucurus* in the wild in Brazil, suggesting that this species uses caudal luring behavior to capture prey. The observations occurred as follows: 1) On 14 April 2007, at 2021 h, in a pond adjacent to Timbó River, Amargosa municipality, state of Bahia; 2) On 29 April 2007, at 0941 h, on the ground of the forest at Igrapiúna municipality, state of Bahia; and 3) On 24 July 2006, at 1440 h, in João Pessoa municipality, state of Paraíba. Similar evidence have been recorded for other Brazilian species such *Tropidodryas striaticeps*, *Bothropoides jararaca*, and *Bothrops jararacussu* (Sazima 1991. Copeia 1991:245–248; Sazima 1993, *op cit.*; Sazima 2006. Aqua, J. Ichthyol. Aquat. Biol. 11:117–124). Although the caudal luring display was observed, there was no case of predation attempts during our observations.

MARCO ANTÔNIO DE FREITAS, Programa de Pós-graduação em Zoologia, UESC (Universidade Estadual de Santa Cruz) CEP 46.500-000 Rodovia Ilhéus/Itabuna, Ilhéus, Bahia, Brazil (e-mail: philodryas@hotmail.com); **THAÍS FIGUEIREDO SANTOS SILVA,** Biogeographia publicações e consultoria ambiental, Rua E quadra D lote 11, Jardim Aeroporto, CEP 42700-000, Lauro de Freitas, Bahia, Brazil (e-mail: biogeographia@yahoo.com.br).

***BOTHROPS* SP. (GR. *ATROX*) (Jararaca/Lancehead). DIET.** Snakes in the *Bothrops atrox* group are widely distributed in Brazilian territory as follows: *Bothrops atrox*, *B. marajoensis*, and *B. brazili* in the Amazon Rainforest, *B. moojeni* in the Cerrado, and *B. leucurus* in the Atlantic Rainforest and Caatinga (Campbell and Lamar 2004. The Venomous Reptiles of the Western Hemisphere. Cornell Univ. Press, Ithaca, New York. 870 pp.). Although other species of South American viperids have specialized diets, snakes in the *B. atrox* group are considered generalists and are known to consume mammals, frogs, lizards, birds, centipedes, and occasionally fishes and other snakes (Campbell and Lamar, *op cit.*; Freitas and Loebmann 2010. Herpetol. Rev. 41:234; Martins et al. 2002. *In* Schuett et al. [eds.], Biology of the Vipers, pp. 307–328. Eagle Mountain Publ., Eagle Mountain, Utah; Martins and Oliveira 1998. Herpetol. Nat. Hist. 6:78–150).

On 20 March 2009, we collected a juvenile male *Bothrops* sp. (gr. *atrox*) (SVL = 501 mm, 24.82 g without prey) in a relictual patch of sub-evergreen tropical nebular rainforest that extends about 150 km across the eastern and northern regions of Chapada da Ibiapaba, in the municipality of Ubajara, state of Ceará, Brazil (03.5042°S, 40.5604°W; datum: WGS84; elev. 851 m). Inside the gut of the specimen we found an intact *Oxyrhopus melanogenys orientalis* (Black-headed Calico Snake; SVL = 390 mm, 16.64 g; Fig. 1). The prey measured ca. 78% of the predator's length and ca. 67% of its body mass. To our knowledge, this is the first record of *B. atrox* preying on snakes of the genus *Oxyrhopus*. The specimen is housed on Universidade de Campinas Natural History Museum 'Prof. Adão J. Cardoso', Campinas, São Paulo, Brazil (ZUEC 3475).

FIG. 1. Juvenile *Bothrops* sp. (gr. *atrox*) with stomach contents, an *Oxyrhopus melanogenys orientalis*.

RODRIGO SAMUEL BUENO GAVIRA, Programa de Pós-graduação em Ciências Biológicas (Zoologia), Departamento de Zoologia, Instituto de Biociências, Laboratório de Herpetologia, Universidade Estadual Paulista, Rio Claro, São Paulo, Brazil, Caixa Postal 199, CEP 13506-970 (e-mail: rodrigogavira@yahoo.com.br); **DANIEL LOEBMANN,** Programa de Pós-graduação em Biologia de Ambientes Aquáticos Continentais, Laboratório de Ecologia de Vertebrados Terrestres, Instituto de Ciências Biológicas, Universidade Federal do Rio Grande, Rio Grande, Rio Grande do Sul, Brazil, Av. Itália, Km 8, Caixa Postal 474, CEP 96201-900 (e-mail: contato@daniel-loebmann.com).

***BUNGARUS CAERULEUS* (Common Krait). SCAVENGING.** We encountered a *Bungarus caeruleus* at Jhadeswar Hill, Ganjam district, Odisha, India (19.4589°N 85.0249°E, datum: WGS84; elev. 83 m) on 12 May 2010 at 2135 h. The krait (ca. 80 cm total length) was found near a hill stream feeding on a dead and decayed snake. After close examination, the prey was identified as a *Coelognathus helena helena*. The dead prey was caught by the middle of the body and was half inside the krait's mouth (Fig. 1). The dead snake was almost the same size or a little smaller than the krait and was swallowed in approximately two minutes. The krait then moved into a heap of boulders near the stream. After interviewing local inhabitants, I learned that a snake had been killed and thrown near the stream three days before.

Kraits are known to feed on frogs, lizards, and snakes (Whitaker and Captain 2004. Snakes of India, the Field Guide. Draco Books, Chennai. 481 pp.). Although scavenging has been documented in several species of snakes under natural conditions, and is considered a prevalent opportunistic foraging strategy for many snakes (DeVault and Krochmal 2002. Herpetologica 58:429–436), it has not previously been reported in *B. caeruleus*.

I thank Satya Narayan Mishra and Saroj Behera for assisting me in the field.

COLOR REPRODUCTIONS SUPPORTED BY THE THOMAS BEAUVAIS FUND

***CARPHOPHIS AMOENUS* (Eastern Wormsnake). DEFENSIVE BEHAVIOR.** Due to their secretive and fossorial habits, little is known about the behavior of *Carphophis amoenus*. The most thorough studies of its ecology are the works of Clark (1970. Univ. Kansas Publ. Mus. Nat. Hist. 19:85–194), Fitch (1999. A Kansas Snake Community: Composition and Changes over 50 Years. Krieger Publ., Malabar, Florida. 165 pp.), and Willson and Dorcas (2004. Southeast. Nat. 3:1–12). Yet, these publications provide little information regarding the behavior of this small snake species. The most commonly reported defensive behaviors exhibited by members of the genus *Carphophis* include the probing of captors with their sharp, hardened tail tip, and releasing a foul-smelling musk (Clark, *op. cit.*; Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Books, Washington, D.C., 668 pp.; Fitch, *op. cit.*;). Recently, however, Diefenbacher and Pauley (2009. Herpetol. Rev. 40:94–95) reported a defensive behavior in *C. amoenus* from West Virginia (USA) that noted an individual that buried its head beneath its body coils, while exposing its tail tip in a vertical orientation. The authors suggested such behavior made the tail more prominent (perhaps mimicking the head), and might confuse potential predators. Here we describe an additional unique behavior that we have not previously witnessed nor read about in the literature, that we believe is exhibited in defense.

On 29 July 2010 near Elon University campus in Alamance Co., North Carolina, USA (36.11859°N, 079.49857°W, datum: NAD 83), an adult male *C. amoenus* (SVL = 204 mm; tail length = 52 mm; 6.5 g) was captured in a drift fence constructed in an upland mixed forest. Once removed from the drift fence trap, the snake was handled for ca. 5–10 min. as morphological data were collected. After its release, the snake only partially buried itself in ground debris, with the tail remaining exposed. At ca. 5 sec. post-release, we lightly stepped on the ground debris near the snake in an effort to expedite concealment. At this point, the snake raised the back 1/4 of its body in a semi-vertical orientation and waved or wagged its tail in an arcing, serpentine fashion for several seconds. It briefly stopped (with tail remaining exposed), until we once again stepped on the layer of fallen leaves near the snake, which caused it to again exhibit this tail waving or wagging behavior for several more seconds. Eventually, the snake stopped waving its tail and moved forward to completely conceal itself beneath the ground debris.

We are uncertain if the observed behavior was meant to distract potential predators from the buried head, or if waving the hardened tail tip may actually deter some species of small predators. Fitch (1999, *op. cit.*) reported that 5.3% of 209 adult *C. vermis* captured in Kansas (USA) were missing tails. He suggested such missing tails were the result of attack by predators, which supports the hypothesis that this behavior is exhibited to distract potential predators from attacking the head. It also supports Diefenbacher and Pauley's (2009) suggestion that the resting orientation they observed was adopted so that predators focus on the tail rather than the head.

JOSHUA M. KAPFER, Departments of Environmental Studies and Biology, Elon University, Elon, North Carolina 27244, USA (e-mail: kapferj@uww.edu); **COLEMAN SLONE,** 2194 Old Paris Road, Lexington, Kentucky 40505, USA (e-mail: cslone@elon.edu).

***COLUBER* (= *MASTICOPHIS*) *FLAGELLUM* (Coachwhip). DIET.** *Coluber flagellum* is known to take a variety of prey items including snakes (Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Institution Press, Washington, D.C. 668 pp.; also *Pituophis catenifer*, Beaman and Harris 2002. Herpetol. Rev. 33:214–215; and *Crotalus viridis*, Tabor and Germano 1997. Herpetol. Rev. 28:90). Here we report a snake as a prey item not previously documented for *C. flagellum*.

In late April 2005, a *C. flagellum* was observed ingesting a live *Trimorphodon lambda* (Sonoran Lyresnake) at the residence of Donna Andress in Nelson, Clark Co., Nevada, USA (35.708°N, 114.823°W). The snakes were initially observed thrashing on the ground, with the *C. flagellum* eventually subduing the *T. lamba* by coiling its body around it. The snakes were photographed and a color print was deposited in the Natural History Museum of Los Angeles County (LACM PC 1430).

***COLUBER* (= *MASTICOPHIS*) *FULIGINOSUS* (Baja California Coachwhip). REPRODUCTION.** *Coluber fuliginosus* ranges from extreme southwestern California south to Cabo San Lucas, Baja California Sur (Grismer 2002. Amphibians and Reptiles of Baja California, Including its Pacific Islands and Islands in the Sea of Cortés. Univ. California Press, Berkeley. 399 pp.). We know of no reports on its reproduction. The purpose of this note is to present the first information on the testicular cycle of *C. fuliginosus*.

A sample of ten adult male *C. fuliginosus* (mean SVL = 1054.5 mm ± 154.0 SD, range: 834–1358 mm) was examined from the herpetology collection of the Natural History Museum of Los Angeles County (LACM), Los Angeles, California. Five *C. fuliginosus* were from Baja California (LACM 2228, 2231, 103250, 103256, 103257) and five were from Baja California del Sur (LACM 19271, 19273, 19276, 103252, 103253). *Coluber fuliginosus* were collected from April–August 1949, 1961, 1964, 1950, 1966, and 1967.

A section of the left testis and vas deferens was removed from each male, embedded in paraffin, cut into 5 µm sections and stained with Harris hematoxylin followed by eosin counterstain. Histology slides were deposited at LACM. Two stages were noted in the testicular cycle: regression, seminiferous tubules contain spermatogonia and interspersed Sertoli cells; spermiogenesis,

seminiferous tubules lined by sperm or clusters of metamorphosing spermatids. The following stages in the testicular cycle were observed by month and sample size: regressed April (2), May (1), June (1); spermiogenesis July (2), August (4). Vasa deferentia contained sperm during all months. The smallest reproductively active male (spermiogenesis in progress) measured 834 mm SVL.

Coluber fuliginosus appears to exhibit an aestival spermatogenesis (St. Girons 1983. Herpetologica 38:5–16) in which spermatogonial divisons commence in spring and spermiogenesis ends in autumn. Similar timing of events in the testicular cycle occurs in the congeners *C. lateralis* (Goldberg 1975. J. Herpetol. 9:361–363) and *C. taeniatus* (Goldberg and Parker 1975. Herpetologica 31:317–322) and has been frequently observed in many North American snakes (Aldridge et al. 2009. Contemp. Herpetol. 2009:1–31).

We thank Christine R. Thacker (LACM) for permission to examine *C. fuliginosus*.

***CORALLUS GRENADENSIS* (Grenada Bank Treeboa, Congo Snake). HABITAT AND ABUNDANCE.** From 3–20 June 2010, we conducted visual encounter surveys for *Corallus grenadensis* on Union Island (St. Vincent and the Grenadines) as in Powell et al. (2007. *In* Henderson and Powell [eds.], Biology of the Boas and Pythons, pp. 374–387. Eagle Mountain Publ., Utah). We had 37 encounters with *C. grenadensis* at eight sites at times from 2000–2345 h. All sites were variants of dry seasonal forest, although dominant species of trees (e.g., *Hippomane mancinella*, *Acacia* sp., *Conocarpus erectus*) varied. Elevations ranged from sea level to 130 m (mean ± SD = 50.8 ± 46.1 m). Snakes were always observed on tall vegetation (≥ 3 m); however, perch heights varied from 0.5 – 15 m (4.0 ± 2.9 m). Most snakes (78%) were young-of-the-year or juveniles. During 31 encounters, boas were actively foraging, moving slowly through vegetation with bodies extended; the others were stationary and coiled on a branch or branches.

Encounter rates of *C. grenadensis* on Union averaged 1.32 ± 0.86 snakes/h. Ideal habitat for *C. grenadensis* consists of edges of natural vegetation mixed with orchard trees (e.g., mango, cacao, nutmeg, breadfruit), in which encounters could exceed 20 boas/h (Henderson 2002. Neotropical Treeboas: Natural History of the *Corallus hortulanus* Complex. Krieger Publ. Co., Malabar, Florida. xiv + 197 pp.; Henderson et al. 2009. S. Amer. J. Herpetol. 4:186–192). Such habitat is lacking on Union. Consequently, encounter rates on Union are not comparable to those in ideal habitats on Grenada. However, when compared with sites on Grenada that are vegetatively similar to Union, encounter rates are much more similar. Mt. Hartman, in extreme southwestern Grenada, consists of dense stands of *Acacia* and mangroves (Henderson 2002, *op cit.*), which are similar to the *Acacia* flatland at some sites on Union (e.g., at Richmond Bay and the coastal mangrove along the road from Clifton to Ashton). Encounter rates at Mt. Hartman averaged 1.87 ± 0.23 snakes/h (Powell et al., *op cit.*). Similarly, the encounter rate at Levera at the extreme northeastern tip of Grenada was 1.62/h (RWH, unpubl. data). Both Mt. Hartman and Levera are in the two driest areas of the island (< 127 cm annually; Grenada Ministry of Agriculture, Land Use Division); annual precipitation on Union is about 100 cm (Adams 1979. Carib. Studies 15:5–45). Although many factors can contribute to low encounter rates (e.g., structure and complexity of vegetation, phase of the moon), based on samples in a variety of habitats on Grenada, Henderson (2002, *op. cit.*) observed that the lowest encounter rates for *C. grenadensis* occurred at elevations >400 m and in very xeric areas. Our comparisons with dry habitats on Grenada suggest that low boa encounter rates on Union likely reflect the reality that xeric habitats on a small, dry island with little topographical relief (Daudin and de Silva 2007. Appl. Herpetol. 4:163–176) support fewer snakes than more mesic habitats.

John S. Parmerlee, Jr., Matthew E. Gifford, Tess A. Bellah, Ehren J. Bentz, Luke G. Chambers, Hayden D. Hedman, Rebecca R. John, Deborah N. Muñiz Pagan, and Mel J. Rivera Rodríguez helped in the field. Mark de Silva and Amos Glasgow identified species of trees for us. Permits to conduct research on Union Island were issued by Mr. Brian Johnson, Director, Department of Forestry, St. Vincent and the Grenadines. Protocols were approved by the Avila University Animal Care and Use Committee. Fieldwork was funded by a grant from the National Science Foundation (USA) to Robert Powell (DBI-0851610).

***CROTALUS ATROX* (Western Diamond-backed Rattlesnake). DIET.** Although the primary diet of *C. atrox* is small mammals, a variety of other food items have been reported, including insects, frogs, toads, lizards, and birds (Rubio 2010. Guide to the Rattlesnakes of the United States and Canada. ECO Herpetol. Publ. Distrib., Rodeo, New Mexico. 307 pp.; Werler and Dixon 2000. Texas Snakes: Identification, Distribution, and Natural History. Univ. Texas Press, Austin. xv + 437 pp.) Although doves are suspected to be part of the diet of *C. atrox*, only a single columbid has been reported and only to generic level (*Columbina* sp.;

FIG. 1. Male *Crotalus atrox* attempting to ingest a freshly killed *Zenaida macroura* (Mourning Dove) at the Indio Mountains Research Station, Hudspeth Co., Texas, USA.

Ernst and Ernst 2003. Snakes of the United States and Canada. Smithson. Inst. Press, Washington, D.C. 668 pp.). Herein, we report a failed predation attempt on a Mourning Dove (*Zenaida macroura*) by a *C. atrox* in the Chihuahuan Desert of Trans-Pecos, Texas.

On 13 October 2010, at 2120 h, an adult male *C. atrox* (SVL = 870 mm; tail length = 50 mm; 366.5 g) was found (Fig. 1) on a brightly moonlit night trying to swallow a freshly killed *Z. macroura* (115.0 g; air temp = 18.1°C; ground temp = 17.0°C). The event was observed in an arroyo surrounded by alluvial slopes covered by Chihuahuan Desert scrub vegetation, ca. 2.5 km SW of Indio Mountains Research Station Headquarters (30.776883°N, 105.016060°W, datum: WGS84; elev. = 1233 m), which is located ca. 40 km SW of Van Horn, Hudspeth Co., Texas, USA. After 20 min, the rattlesnake had swallowed the dove's head and neck, but was struggling to pass the breast section, which is the widest part of the bird's body. Eventually, the rattlesnake ceased the ingestion process, regurgitated the dove's anterior portion, and then moved away from the scene. Although the relative prey mass was low (= 0.3), we suspect that the snake suspended its ingestion attempt because of physical constraints imposed by the dove's anatomy, most likely the breast width.

VICENTE MATA-SILVA (e-mail: vmata@miners.utep.edu), **JERRY D. JOHNSON** (e-mail: jjohnson@utep.edu), **ROSS COUVILLON, WILLIAM LUKEFAHR,** and **ARTURO ROCHA,** Department of Biological Sciences, University of Texas at El Paso, El Paso, Texas 79968, USA.

***CROTALUS LEPIDUS* (Rock Rattlesnake). FEEDING BEHAVIOR.** The diet of *Crotalus lepidus* reportedly includes arthropods, frogs, small rodents, snakes, and lizards (Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Institution Press, Washington, D.C. 668 pp.). From the limited information on feeding behavior in the wild, it is assumed that *C. lepidus* consumes nearly any small animal that it can subjugate, although lizards, because of their usual abundance in habitats favored by *C. lepidus*, are probably the primary food item (Armstrong and Murphy 1979. Univ. Kansas Mus. Nat. Hist. Spec. Publ. 5:1–88; Beaupre 1995. Herpetologica 51:45–56). It has been stated that *C. lepidus* strike lizards on their body and hold them until comatose and, therefore, no poststrike trailing behavior occurs; whereas mice are struck, released, and later trailed (Chiszar et al. 1986. J. Comp. Psychol. 100:368–371). Here we report a wild *C. lepidus* striking, trailing, and consuming a *Cophosaurus texanus* (Greater Earless Lizard), at a site located in the Chihuahuan Desert of Trans-Pecos, Texas.

On 18 July 2010, at 1020 h, an adult male *C. lepidus* (SVL= 560 mm; tail length = 65 mm; 140 g), fitted with a radio-transmitter (Holohil Ltd. SB-2), was being tracked at the Indio Mountains Research Station, Hudspeth Co., Texas, USA (30.754507°N, 105.020513°W, datum: WGS84; elev. = 1214 m), in an area of rocky mountainous substrate covered by Chihuahuan Desert scrub vegetation. The snake, apparently unfazed by our presence, was situated in the open near a dying adult male *C. texanus* that had been recently envenomated, as evidenced by two bloody puncture wounds on its back. A few moments later the rattlesnake, while exhibiting tongue-flicking and frenzied searching behavior, located the lizard, grabbed it by the head, and dragged it under a nearby Fragrant Mimosa (*Mimosa borealis*). The snake then proceeded to ingest the lizard headfirst (Fig. 1). When about half the lizard's body was left exposed, the snake stopped the swallowing process and regurgitated it, possibly due to positioning

FIG. 1. Adult *Crotalus lepidus* ingesting a freshly killed *Cophosaurus texanus* (Greater Earless Lizard) at the Indio Mountains Research Station, Hudspeth Co., Texas, USA.

COLOR REPRODUCTIONS SUPPORTED BY THE THOMAS BEAUVAIS FUND

problems that lead to difficulty passing the widest section of the lizard's body. Immediately thereafter, the snake reinitiated the ingestion process and fully consumed the lizard in about 20 min. To our knowledge, this is the first report demonstrating that lizards, like rodents, may be struck, released, and trailed, before being consumed by *C. lepidus*.

Partial funding for field work was supplied by a grant from T&E Inc., the Joseph Family Trust Fund, a G. A. Krutilek Fellowship, and a F. B. Cotton Trust Scholarship to V. Mata-Silva.

***HETERODON NASICUS* (Western Hog-nosed Snake). DIET.** *Heterodon nasicus* is a medium-sized (total length to 154 cm but usually <80 cm) colubroid snake native to prairie habitats of central North America (Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Inst. Press, Washington, D.C. 668 pp.). This species is a mildly venomous, opistoglyphous, nonconstricting dietary generalist that is known to consume a wider range of vertebrate prey items, including amphibians, small mammals, lizards and eggs of turtles and birds, than its congeners. Platt (1969. Univ. Kansas Mus. Nat. Hist. Publ. 18:253–420) reported that *H. nasicus* feeds on lizard eggs, but did not identify the species. Here we report a juvenile *H. nasicus* feeding repeatedly on eggs of *Aspidoscelis sexlineata* (Six-lined Racerunner), a previously unrecorded dietary component.

At 0845 h on 25 June 2010, a juvenile *H. nasicus* (male, SVL = 19.5 cm, 9.5 g) was found in a sand blowout at Thomson-Fulton Sand Prairie, Carroll Co., Illinois, USA (41.938562°N, 90.109196°W; datum WGS 84). The snake was exposed in open sand and had a cloacal temperature of 28.8°C. Palpation of the gut caused regurgitation of two oblong lizard eggs with leathery shells, both of which were ruptured so that the yolk was exposed. This individual was marked, released, and then recaptured the following day in approximately the same location, and again its gut contained two ruptured lizard eggs.

We infer that these eggs were depredated from a nest of *A. sexlineata* because this is the only lizard known to occur in Carroll Co. and is common at our study site. Trauth (1983. Am. Midl. Nat. 109:289–299) described the nesting ecology of *A. sexlineata* and reported that females use communal nesting

grounds, where egg density can be up to 10/m^2, and females may return to favored nesting sites year after year. This spatial and temporal predictability of *A. sexlineata* eggs may underlie the potential importance of this food source for young hog-nosed snakes.

***MASTIGODRYAS BODDAERTI* (Boddaert's Tropical Racer). DEFENSIVE BEHAVIOR.** Defensive behavior in snakes is characterized by a series of tactics, ranging from immobility to biting, that act in sequence during a predatory event (Endler 1986. *In* Feder and Lauder [eds.], Predator Prey Relationships: Perspectives and Approaches from the Study of Lower Vertebrates, pp. 109–134. Univ. Chicago Press, Chicago, Illinois; Greene 1988. *In* Gans and Huey [eds.], Biology of Reptilia, Vol 16, Ecology B, Defense and Life History, pp. 1–152. Alan R. Liss, Inc, New York; Martins 1996. Anais de Etologia 14:185–199). *Mastigodryas boddaerti* is a terrestrial and diurnal colubrid snake that occurs in tropical areas of the Amazon, Cerrado, and Caatinga biomes of South America (Colli et al. 2002. *In* Oliveira and Marquis [eds.], The Cerrados of Brazil: Ecology and Natural History of a Neotropical Savanna, pp. 223–241. Columbia Univ. Press, New York; Cunha and Nascimento 1993. Boletim do Museu Paraense Emílio Goeldi Vol. 9[1]:1–191); Martins and Oliveira 1998. Herpetol. Nat. Hist. 6:78–150). During a field trip to the municipality of Caxingó, state of Piauí, northeastern Brazil (3.359926°S, 41.75247°W, datum: WGS84; elev. 106 m), I observed a sequence of defensive behaviors in a *M. boddaerti*. Here, I described them based on the classification of Greene (*op. cit.*).

On 30 July 2010, at approximately 2230 h, I observed an adult *M. boddaerti* coiled asleep 1.3 m high in the branches of a *Mimosa caesalpiniifolia* tree (*1 – inaccessibility*). When I moved the branches where the snake was located, it tried to escape among the branches (*2 – locomotor escape*). Then, when I grabbed the snake at mid-body, it started to vibrate its tail (*3 – tail vibration*). After I removed it from the tree branches it rotated and thrashed its body, trying to escape (*4 – body thrashing, 5 – rotate body*). The snake succeeded in getting free, but I immediately caught it by the tail, at which time the tail was autotomized (*6 – tail breakage*). Finally, the snake attacked and bit me (*7 –strike, 8 –bite*).

As seen in this event, *M. boddaerti* exhibits a series of defensive mechanisms, acting at different stages of a predatory event. This is the first report of tail autotomy in *M. boddaerti*, but this defensive tactic has been documented in multiple snake genera from several different families (*e.g., Mastigodryas, Scaphiodontophis, Dendrophidion, Coronella, Hemorhois, Macroprotodon*, and *Rhinechis* in the Colubridae; *Malpolon* in the Psammophidae; *Natrix* in the Natricidae; *Coniophanes* in the Dipsadidae; and *Vipera* in the Viperidae; Martins 1998, *op. cit.;* Pleguezuelos et al. 2007. Contrib. Zool. 76:179–186; Savage and Slowinski 1996. Biol. J. Linn. Soc. 57:129–194). As noted by Martins (1998, *op. cit.*), the diversity of snakes that exhibit tail autotomy might be explained by shared phylogeny or, more likely, this trait might have evolved independently in multiple lineages as a convergent response to similar predation pressures.

I thank Daniel Loebmann for suggestions on the manuscript.

IGOR JOVENTINO ROBERTO, Sertões Consultoria Ambiental e Assessoria, Rua Bill Cartaxo 135, Bairro Sapiranga, CEP: 60833-185, Fortaleza, Ceará, Brazil; e-mail: igorjoventino@yahoo.com.br.

***MICRURUROIDES EURYXANTHUS* (Sonoran Coralsnake). PREDATION.** There are occasional records of spiders eating snakes and other small vertebrates (Greene 1988. *In* Gans and Huey [eds.], Biology of the Reptilia, vol. 16, Ecology B. pp. 1–152. Alan R. Liss, New York; Kaston 1965. Amer. Midl. Nat. 73:336–356; McCormick and Polis 1982. Biol. Rev. 57:29–58). Many records are of very large spiders (e.g., tarantulas, Theraphosidae) eating small snakes, but there are also instances of smaller spiders catching and preying (or even scavenging) upon small snakes and other vertebrates. For example, Lazcano et al. (2005. Herpetol. Rev. 36:186) and Gerald (2006. Herpetol. Rev. 37:480) reported small snakes being consumed by a fishing spider, *Dolomedes tenebrosus* (Pisauridae). Zippel and Kirkland (1998. Herpetol. Rev. 29:46) found a dead *Opheodrys aestivus* wrapped in the silk of a Golden Orb Weaving Spider, *Nephila clavipes* (Nephilidae), high above the ground, but this may not have involved predation. Although these records suggest several families of spiders may feed upon snakes, most reports of snake predation from medium-sized spiders are of cobweb-weaver (comb-footed) spiders, Theridiidae. Kaston (*op. cit.*) mentioned that some members of the Theridiidae have strong webs and may fling silk over the bodies of snared prey. Theriids (especially *Latrodectus*) tend to take large prey (Hódar and Sánchez-Piñero 2002. J. Zool. Lond. 257:101–109; McCormick and Polis, *op. cit.*).

Pruett and Jadin (2010. Herpetol. Rev. 41:99) documented a theriid, *Steatoda* sp., preying on a *Tantilla gracilis* in Texas. Hall and Johnson (2008. Prairie Nat. 39:157–158) reported *Storeria occipitomaculata* in the web of a *Theridion* sp., but the authors thought the snake might have been entangled while seeking invertebrate prey in the web, and no signs of predation were observed. Most records of theriid spiders preying upon snakes refer to members of the genus *Latrodectus* (commonly known as widow, button, and redback spiders), all of which are morphologically similar and highly venomous. Neill (1948. Herpetologica 4:158) reported *L. mactans* (Southern Black Widow) preying upon the small snakes *Opheodrys aestivus* and *Storeria dekayi*, in Georgia, USA. Ervin and Carroll (2007. Herpetol. Rev. 38:468) reported a dead *Hypsiglena chlorophaea* in the web of *L. mactans* in Yavapai Co., Arizona, USA. Bayliss (2001. Herpetol. Rev. 32:48–49) reported three incidences (two direct observations and one

FIG. 1. Adult female *Lactrodectus* (presumably *L. hesperus*) feeding on *M. euryxanthus*, near Superior, Arizona, USA.

COLOR REPRODUCTIONS SUPPORTED BY THE THOMAS BEAUVAIS FUND

reported to him) of Geometrid Button Spiders (*L. geometricus*) preying upon small snakes, *Lamprophis fulginosus* and *Crotaphopeltis hoamboaei*, in South Africa. McCormick and Polis (*op. cit.*), they also report on an Australian Redback Spider (*L. hasselti*) preying on a *Pseudechis porphyriacus*. A recent internet search revealed several stories with photographs of *Lactrodectus* capturing and feeding on small snakes.

Coralsnakes have rarely been documented as prey for invertebrates. Roze (1996. Coral Snakes of the Americas: Biology, Identification, and Venoms. Krieger Publ. Co., Malabar, Florida. 328 pp.) suggested that coralsnakes may fall prey to army ants. Recently, Nunes (2010. Herpetol. Rev. 41:367–368) reported a tarantula, *Pachistopelma rufonigrum* (Theraphosidae) attempting to prey on a *Micrurus ibiboboca*, in Brazil. Here we describe two instances of presumed predation by *Latrodectus* on the Sonoran Coralsnake (*Micruroides euryxanthus*) in Arizona, and discuss predation of small snakes by *Latrodectus*.

On 16 July 2010, one of us (PAS) was pressure washing a walkway to an outhouse in Sabino Canyon, Santa Catalina Mountains, near Tucson, Pima Co., Arizona, USA, when a subadult *Micruroides euryxanthus* wrapped in a spider web was dislodged. The snake had its head and forebody tightly wrapped in spider silk. Western Black Widow Spiders (*L. hesperus*) are common in this area and often build their messy webs near these structures.

On 29 August 2010, a second instance of a *L. hesperus* preying upon a *M. euryxanthus* was documented (Fig. 1). The incident was reported by visitors to the Boyce Thompson Arboretum, near Superior, Pinal Co., Arizona, USA, and witnessed by three of us (ADK, LLCJ, and PW). The dead snake was also a subadult. It was suspended about 10 cm above the walkway, under an overhang just outside the entrance of the Visitor's Center. The spider was seen feeding on the snake, near the tail end. The posterior one-third of the body and tail was collapsed, suggesting the spider had liquefied and sucked out the contents of that portion of the snake. As in the previous observation, the head and forebody of the snake were wrapped in silk. This was also reported in one instance by *L. geometricus* (Bayliss, *op. cit.*) and by Pruett and Jadin (*op. cit.*) for *Steotoda*.

There also are numerous reports of *Latrodectus* feeding on lizards. Painter and Kamees (2010. Herpetol. Rev. 41:227) discussed predation on a neonate of the lizard *Phrynosoma hernandesi* by *L. hesperus* in New Mexico. They also provide a literature review of several reports of lizards in the diet of *Latrodectus* spp., including five instances of lizard predation by *L. liliana* in Spain (Hódar and Sánchez-Piñero, *op. cit.*). They note that lizard remains (unlike invertebrate prey) were discarded from the web, presumably because the remains attract ants, so vertebrate prey might be an underestimated component of the diet. *Micruroides euryxanthus* feeds primarily on small snakes and lizards (Roze, *op cit.*; Stebbins 2003. Western Reptiles and Amphibians. Houghton Mifflin, Boston, Massachusetts. 533 pp.), so it seems unlikely that the snakes we observed were attempting to eat the spiders or other invertebrates in the web. It is more likely the snakes were simply entangled in the low-lying webs while active on the surface.

Based on the observations detailed above, as well as our own, a scenario emerges wherein small squamate prey may not be so unusual for *Latrodectus*, and may actually be part of the typical (albeit less frequently encountered) prey, along with large invertebrates. Adult female members of this genus seem well-adapted to subduing and feeding on small vertebrates, at least opportunistically. The webs of *Latrodectus* are often on vegetation or under overhangs and 10–50 cm above the surface of the ground. The spider sets highly adhesive hunting threads to the substrate to target mostly nocturnal prey. If large insects or small vertebrates encounter the web, they struggle, and become entangled. The strong, sticky strands of silk become detached from the surface, and the animal may become tangled higher up in the web, where it cannot gain purchase from the surface to help it escape. The spider can help subdue the animal's attempt to free itself by further wrapping it in silk (perhaps targeting the head area) and can safely immobilize and dispatch the snake or lizard with its extremely powerful venom (and liquefy the contents for feeding). Vertebrate prey remains may then be discarded to avoid ants in the web. Although there may be variations on this theme, large female *Lactrodectus* seems quite capable of dealing with small squamates. Because vertebrates are discarded after feeding, it is likely they are underreported as prey; even so, there are far more records of *Latrodectus* feeding on snakes and lizards than for other similarly-sized spiders.

***MICRURUS SURINAMENSIS* (Aquatic Coralsnake). OPHIOPHAGY.** *Micrurus surinamensis* is a primarily aquatic, diurnal-nocturnal coralsnake, inhabiting a variety of wet habitats in the Amazon from Surinam to Bolivia (Campbell and Lamar 2004. The Venomous Reptiles of the Western Hemisphere. Cornell Univ. Press, Ithaca, New York. 870 pp.). This species feeds primarily on fishes (*Callichthys*, *Gymnotus*, *Synbranchus*; Cunha and Nascimento 1978. Publ. Avul. Mus. Par. Emílio Goeldi 31:168–170; Roze 1996. Coral Snakes of the Americas: Biology, Identification, and Venoms. Krieger Publ. Co., Malabar, Florida. 340 pp.), but is also reported to eat lizards occasionally (Martins and Oliveira 1999. Herpetol. Nat. Hist. 6:62–63). In South America, the snake genera most frequently consumed by coral snakes are *Atractus* and *Liophis* (Roze 1996, *op. cit.*). On 13 May 2006, we collected an adult male *M. surinamensis* (MCN-R 2740; total length = 1011 mm; SVL = 941 mm; midbody diameter = 24.3 mm) on the road in Porto Trombetas, Oriximiná municipality, Pará, Brazil (1.833°S, 56.517°W, datum SAD 69; elev. 83 m) that contained an adult female *Liophis reginae* (MCN-R 2743; total length = 570 mm; SVL = 420 mm; midbody diameter = 15.2 mm) in its stomach. Ophiophagy has been reported in many coralsnake species (Marques and Sazima 1997. Herpetol. Nat. Hist. 5:88–93), but to date no record of this habit has been reported for *M. surinamensis*. We suggest that this record represents an occasional prey item in the diet of this aquatic coralsnake.

ROBERTA RICHARD PINTO, Departamento de Vetebrados, Museu Nacional, Universidade Federal do Rio de Janeiro, Quinta da Boa Vista, s/n, 20940-040, São Cristóvão, Rio de Janeiro, Rio de Janeiro, Brazil (e-mail: robertarich@gmail.com); **MARCELO GOMES**, Departamento de Vertebrados, Museu Nacional, Universidade Federal do Rio de Janeiro, Quinta da Boa Vista, s/n, 20940-040, São Cristóvão, Rio de Janeiro, Rio de Janeiro, Brazil (e-mail: gomes@gmail.com); **RONALD CARVALHO JR.,** Táxon Meio Ambiente, Estudos e Projetos Ltda, 30575-210, Belo Horizonte, Minas Gerais, Brazil (e-mail: ronald@taxonmeioambiente.com.br).

***NERODIA SIPEDON* (Northern Watersnake). RESPONSE TO MOBBING BY FISH.** Mobbing of snakes by birds (Fitch 1999. A Kansas Snake Community: Composition and Changes over 50 Years. Krieger Publ. Co., Malabar, Florida. 165 pp.) and mammals (particularly primates and rodents; Gursky 2005. Int. J. Primatol. 26:207–221; Owings and Coss 1977. Behaviour 62:50–69) is a commonly reported phenomenon. In the wild, mobbing may be a common occurrence; Timber Rattlesnakes studied in New York were harassed on average once every 6.4 days by birds (Clark 2005. Behav. Ecol. Sociobiol. 59:259–261). However, reports of mobbing of snakes by animals other than sciurid rodents and birds are relatively rare. Furthermore, mobbing of potential predators (including non-snakes) by fish is extremely rare (Dominey 1983. Copeia 1983:1086–1088). Here, we report the escape behavior of *Nerodia sipedon* in response to mobbing by a group of fish.

On 28 May 2010, at 1131 h, one of us (MR) observed an adult *N. sipedon* (ca. 70 cm total length) laterally undulating along the bottom of Devil's Lake in Devil's Lake State Park in Sauk Co., Wisconsin, USA (43.426031°N, 89.728481°W, datum: NAD83). The snake was found on the northeastern shoreline approximately 2 m from the shore in water approximately 0.75 m deep. The water was clear and the bottom was composed of small gravel (<3 cm in diameter), providing an unobstructed view of the snake. No spawning beds (of any species of fish) were observed anywhere along the shore. Within 5 sec of the initial observation of the snake, approximately 6–8 *Micropterus salmoides* (Largemouth Bass) approached the snake and surrounded it on both sides. The bass appeared to be about 15–20 cm in length. The bass approached the snake to within about 2–10 cm and oriented towards the head of the snake. The snake paused for ca. 5 sec, swam to the surface to obtain air, and then swam down to the lake bed and laterally undulated away at a faster rate than prior to the bass's approach. During this entire observation, the bass followed the movements of the snake, staying near the sides of the snake's head, but never in front of the head. The snake continued moving parallel to the shore and the bass continued to follow the snake for a minimum of 4 m until the group was out of the observer's view. As the bass continued to follow the snake, the bass got closer to the snake's head but made no attempt to bite the snake. The snake made no attempt to strike or otherwise ward off the bass, other than to swim away faster along the bottom of the lake.

Attempted predation or nest defense would be likely interpretations of the bass' behavior, however, we reject these hypotheses. Although Largemouth Bass are documented predators of Northern Watersnakes (Gibbons and Dorcas 2004. North American Watersnakes: A Natural History. Univ. Oklahoma Press, Norman. 438 pp.), none of the bass observed harassing the snake appeared to be large enough to consume the snake. Additionally, it would be logical that the fish were harassing a predator in their breeding grounds (Dominey, *op. cit.*), however, many of the fish involved were of non-breeding size and no spawning beds were observed. Another possible hypothesis is that the fish were following the snake in an attempt to capture prey flushed by the snake, however, no feeding by the bass was observed. Deterring a possible predation attempt by group harassment or mobbing is the most consistent hypothesis that fits with our observations. It is interesting to note that many of the bass were within possible prey size range for the snake.

In many examples of mobbing, actual contact (i.e., pecking and biting) with the snakes has been observed (Fitch, *op. cit.*); in this instance, we did not observe contact between the fish and the snake. The snake's response was similar to what has been observed for other species of snakes while being mobbed (Fitch, *op. cit.*). No attempt to orient towards the bass or strike the bass was made, despite the fact that several fish were within striking distance of the snake's head. The most common result of harassment is to abandon the foraging grounds (Clark, *op. cit.*) and relocate to new foraging grounds.

We thank Brian D. Horne for his comments on the manuscript.

NOAH J. ANDERSON, Department of Biological Sciences, University of Wisconsin-Baraboo/Sauk County, 1006 Connie Road, Baraboo, Wisconsin 53913, USA (e-mail: noah.anderson@uwc.edu); **MARK A. ROZMARYNOWSKI,** Learning Resource Center 104A, University of Wisconsin-Stevens Point, Stevens Point, Wisconsin 54481, USA.

***NOTECHIS SCUTATUS* (Tiger Snake). PREDATION.** Terrestrial-aquatic ecotones act as connection lines for species fluxes along river corridors (Pinay et al. 1990. *In* Naiman and Décamps [eds.], The Ecology and Management of Aquatic-Terrestrial Ecotones, pp. 141–169. Parthenon Publ. Group, Carnforth, UK). Rainbow Trout (*Onchorhyncus mykiss)* are distributed globally (MacCrimmon 1971. J. Fish. Res. Board. Can. 28:663–704) and this has led to countless diet studies indicating they predominantly prey upon fish and aquatic and terrestrial invertebrates (Buria et al. 2009. Rev. Chil. Hist. Nat. 82:3–15; Kido et al. 1999. Pac. Sci. 53:242–251). Terrestrial vertebrates are not a common prey item of Rainbow Trout.

A Rainbow Trout measuring 30 cm fork length was captured at 1230 h using a backpack electrofisher on the 19 April 2010 in the Cotter River (35.387°S, 148.866°E; datum WGS84), Australian Capital Territory. The individual was using submerged fallen timber as refuge in approximately 50 cm of water when captured. Upon dissection, it was noted that the stomach was extremely distended with stomach content analysis revealing a 26 cm (total length) juvenile *Notechis scutatus*. The intact snake dermis indicated that the snake had recently been ingested.

Rainbow Trout have been recorded preying on several species of reptiles including a snake of the genus *Natrix*, a *Podarcis muralis* (Common Wall Lizard) and an *Anguis fragilis* (Slow Worm; Bernini et al. 2006. Acta. Herpetol. 1:61–63), a *Eulamprus tympanum* (Southern Water Skink; Lintermans 1992. Herpetofauna 22:34), and a *Leiolopisma mettalicum* (Metallic Skink; Kido et al., *op. cit.*). Another observation recorded a Rainbow Trout attacking a *Natrix natrix* (Grass Snake) for five minutes after which the snake was able to free itself. The same study noted a Brown Trout (*Salmo truttta)* that had eaten a *N. natrix* and died in the process (Eder et al. 1998. Herpetozoa 1:69–71).

Notechis scutatus is found in Queensland, New South Wales, Australian Capital Territory, Victoria, South Australia, and Western Australia and is often associated with water bodies as frogs constitute a high proportion of its diet (Cogger 2000. Reptiles and Amphibians of Australia. Reed New Holland, Sydney. 808 pp.). Rainbow Trout are opportunistic visual predators (Buria et al., *op. cit.*; Kido et al., *op. cit.*). The predation on reptiles by salmonids is an occasional phenomenon and not considered a threat to populations living along a watercourse (Bernini et al., *op. cit.*).

I thank Tim Kaminskas for his assistance in the field and the IAE writing group for useful comments on the first draft of this note.

***PANTHEROPHIS SPILOIDES* (Gray Ratsnake). ATTEMPTED PREDATION AND AQUATIC ESCAPE BEHAVIOR.** There are few observations of fish predation on snakes, with most focused on *Micropterus salmoides* (Largemouth Bass; Szelistowski and Meylan 1996. Herpetol. Rev. 27:204–205). Herein, we describe a predatory encounter between a *Pantherophis spiloides* and a *Lespisosteus osseus* (Longnose Gar). The observation took place at ~1900 h on 8 July 2010, in a large ditch along IL Hwy 100 and bordering southwest edge of the Raging Rivers Water Park (Grafton, Madison Co., Illinois, USA; 38.96822°N, 90.40142°W; datum NAD 1984). The ditch continued under a large culvert near which several large (~60–90 cm) gar were basking, and continued west into the Mississippi River. We observed a *P. spiloides* (ca. 90 cm total length) swimming in this ditch. Upon reaching the proximity of the culvert, one of the gar attacked the snake. The gar grabbed the snake's tail which broke off, allowing the snake to escape. We could not tell if the fish consumed the tail. The snake raised its head high above the water and began to skip across the water very rapidly until it reached the shore. This skipping behavior emulated that of the side-winding behavior used by *Crotalus cerastes* to navigate sand dunes, only it was used across the surface of the water and performed rapidly enough to avoid sinking. The behavior was effective in that the snake did escape. This appears to be the only observation of attempted predation on a snake by gar and to our knowledge, is the first report of this escape behavior by *P. spiloides*.

***PELAMIS PLATURA* (Yellow-bellied Seasnake). PREDATION.** *Pelamis platura* is unpalatable to many predatory fish (Rubinoff and Kropach 1970. Nature 228:1288–1290; Weldon 1988. Zool. Sci. 5:443–448) and documented instances of attempted predation on *P. platura* in the wild are rare. Crabs (likely *Ocypode* spp.) have been found scavenging dead *P. platura* (Duellman 1961. Univ. Kansas Public Mus. Nat. Hist. 15:1–148), and two marine mammals (*Hydrurga leptonyx* and *Zalophus californianus*) have been seen regurgitating *P. platura* and thereafter appearing sick (Heatwole and Finnie 1980. Herptofauna 11:24; Reynolds and Pickwell 1984. Copeia 1984:786–789). Moreover, *P. platura* has been observed being picked up and subsequently dropped by birds on two occasions, once by a Lava Gull (*Larus fuliginosus*; Reynolds and Pickwell 1984. Copeia 1984:786–789) and once by a Frigatebird (*Fregata magnificens*; Wetmore 1965. Smithson. Misc. Coll. 150:75). In the latter case, the author observed a frigatebird "pick up a sea snake [*P. platura*] swimming at the surface and carry it, as it twisted and coiled, for a short distance with other frigates in close pursuit, and then finally let it drop." Herein, we report a very similar event in Bahía de Culebra near las Islas Pelonas in Guanacaste, Costa Rica.

On 8 June 2010, at 0835 h, we observed a Frigatebird dive toward the sea, grab an adult *P. platura* at the surface with its beak, carry it partially out of the water for ca. 2 sec, and then drop it. The frigatebird then circled around and dove again in the same area, but stopped partway and flew off before reaching the water. We investigated the area for 10 min via boat and could not find the *P. platura* suggesting that it survived the "attack" and likely swam down to escape. Whether such events actually indicate attempted predation remains unknown. Predation on *P. platura* is thought to be minimal due to its apparently noxious flesh and aposematic coloration (Heatwole 1975. *In* W. A. Dunson [ed.], The Biology of Sea Snakes, pp. 230–250. University Park Press, Baltimore, Maryland). However, frequently we have observed scars on the Costa Rican *P. platura*, including some that are V-shaped or diagonal (Fig. 1), which suggests such incidents with birds may be relatively common in this area. Weldon (1988. Biotropica 20:174–176) suggested that such scars on *P. platura* probably were caused by humans (e.g., boat propellers). However, given the observations of birds picking up *P. platura* from the water and the shape of the injuries sustained, we consider attempted predation by birds to be a more likely explanation for these scars.

***PELAMIS PLATURA* (Yellow-bellied Seasnake). MATING BEHAVIOR.** The wide range of *P. platura* includes tropical and subtropical waters of the Western Hemisphere (Campbell and Lamar 2004. The Venomous Reptiles of the Western Hemisphere. Cornell University Press, Ithaca, New York, xviii + 870 + 28 pp.; Sasa et al. 2010. *In* Wilson et al. [eds.], Conservation of Mesoamerican Amphibians and Reptiles, pp. 511–603 Eagle Mountain Publishing, LC., Eagle Mountain, Utah).The reproductive cycle of this species apparently is continuous throughout the year, but two birthing peaks have been reported, one in December and January and other in July and August (Solórzano 2004. Serpientes de Costa Rica / Snakes of Costa Rica. Editorial INBio, Santo Domingo Heredia, Costa Rica, 791 pp.). On a sunny morning in August 2009 we observed two *P. platura* copulating while floating on the surface of calm water (Fig. 1) at Archipiélago Murciélago,

COLOR REPRODUCTIONS SUPPORTED BY THE THOMAS BEAUVAIS FUND

***RENA* (= *LEPTOTYPHLOPS*) *HUMILIS* (Western Threadsnake). PREDATION.** Reported predators of *Rena humilis* include scorpions, snakes, and coyotes (Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Inst. Press, Washington, D.C. 668 pp.). Herein we report the first record of predation on *R. humilis* by the Pallid Bat, *Antrozous pallidus*.

On 1 May 2009, at 1600 h, a freshly-killed adult *R. humilis* was found under an *A. pallidus* night roost, along with various arthropod remains, at the entrance to the bathroom facility on Indio Mountains Research Station (IMRS), located in the Trans-Pecos region of the Chihuahuan Desert, ca. 40 km SW of Van Horn, Hudspeth Co., Texas, USA (30.782778°N, 105.015278°W, datum: WGS84; elev. 1233 m). The snake had been partially consumed, thereby missing about one-third of the posterior portion of its body. Nocturnal predation on small terrestrial reptiles by *A. pallidus* is due to the bat's unusual behavior of gleaning prey from the ground and low vegetation (Lenhart et al. 2010. Southwest. Nat. 55:110–115). The snake was deposited in the Herpetology Collection, Laboratory for Environmental Biology, Centennial Museum, University of Texas at El Paso (UTEP 20011).

We thank C. S. Lieb, R. G. Webb, and H. W. Greene for kindly providing some of the literature sources.

VICENTE MATA-SILVA (e-mail: vmata@miners.utep.edu), and **JERRY D. JOHNSON,** Department of Biological Sciences, University of Texas at El Paso, El Paso, Texas 79968, USA (e-mail: jjohnson@utep.edu).

***STORERIA DEKAYI TEXANA* (Texas Brownsnake). DEATH FEIGNING.** Death feigning or thanatosis in snakes is defined as completely reducing responsiveness to stimuli while displaying secondary behaviors (coiling, releasing musk and feces, etc.) to thwart potential predators (Carpenter and Ferguson 1977. *In* Gans and Tinkle [eds.], Biology of the Reptilia, Vol. 7, pp. 335–554. Academic Press, New York). Liner (1977. Trans. Kansas Acad. Sci. 80:81–82) and Hayes (1987. Herpetol. Rev. 18:16–17) each reported that a few individual adult *Storeria dekayi* will lay upside-down and motionless following extensive prodding. Neonates will lie upside-down and motionless when placed in water within a few days after birth (Gerald 2008. Anim. Behav. 75:647–654). Here we provide the first report of an adult *S. dekayi* exhibiting thanatosis complete with secondary display behaviors.

On 10 September 2010 at 1950 h, we discovered a sub-adult *S. dekayi* (SVL = ca. 21 cm) on Saline River Road in Ellis Co., Kansas, USA (39.10398°N, 99.04007°W; datum: WGS84). When the snake was approached while on the road, it immediately released cloacal contents, spread contents over most of the body via violent writhing, and coiled. The snake was handled and flipped on its back where it remained upside-down and motionless for over 90 sec (Fig. 1). The snake then righted itself and remained motionless for several seconds before attempting to actively escape. Temperature of the road was 24.4°C. Two out of five other adult and sub-adult *S. dekayi* captured in the area over the next two days also spread cloacal contents over the body and remained motionless, but did not flip upside-down.

Death feigning has been shown to be influenced by temperature, size, locomotor performance, and distance from predators (Burghardt and Greene 1988. Anim. Behav. 36:1842–1844; Gerald 2008, *op. cit.*). This is the first report of an adult *S. dekayi* displaying death feigning immediately following encounter with a potential predator. Moreover, this is the first report on the use of

FIG. 1. *Storeria dekayi texana* from Ellis Co., Kansas, USA, exhibiting death-feigning behavior.

secondary behaviors that presumably adds to the effectiveness of the death feigning display that is often attributed to snakes of the genus *Heterodon* (e.g., Gehlbach 1970. Herpetologica 26:24–34). The scarcity of published reports and the lack of personal observations of death feigning behaviors in adult *S. dekayi* suggest that the presence of this behavioral strategy in this species is highly variable among individuals and populations and is likely not nearly as common as reported in other snake species (e.g., *Heterodon*).

GARY W. GERALD, Department of Biology, Nebraska Wesleyan University, Lincoln, Nebraska 68504, USA (e-mail: ggerald@nebrwesleyan.edu); **MICHAEL P. GRAZIANO**, University of Nebraska, Omaha, Nebraska 68182, USA (e-mail: mpgraziano@gmail.com).

***TANTILLA RUBRA* (Red Black-headed Snake). MAXIMUM SIZE.** The maximum size reported for *Tantilla rubra* based on an examination of 48 adult specimens with complete tails from Mexico and Guatemala was 500 mm (Dixon et al. 2000. Southwest. Nat. 45:141–153). A maximum total length of 594 mm, with a maximum tail length of 130 mm is also recorded (Wilson et al. 2000. Cat. Amer. Amphib. Rept. 720.1–720.3).

On 20 September 2007, at 1205 h, WF and TB found a road-killed female *T. rubra* (SVL = 545 mm; tail length = 114 mm; total length = 659 mm; 43 g) in Tamaulipas, Mexico. This exceeds the maximum recorded total length for the species by 65 mm (10%). The locality was on the "old" Federal Mexican Highway 101 (a new four lane Federal Mexican highway was opened in 2004, diverting the majority of the traffic through the Sierra Madre Oriental between Jaumave and Cd. Victoria, bypassing this locality; however both highways retain the designation 101), 25.5 km NNE of the town of Jaumave (23.618889°N, 99.281667°W, datum: WGS84; elev. 1016 m). This locality is approximately at the border of the Jaumave-Victoria municipality line on the interior western slope of the Sierra Madre Oriental that separates the Jaumave valley from the Gulf Coastal Plain. The habitat in the area is a transition zone between arid thorn scrub of the Jaumave valley and oak forest at higher elevations in the Sierra Madre. The specimen was deposited in the collection at Universidad Autónoma de Nuevo León, Facultad de Ciencias Biológicas, preserved collection (UANL 6460).

Fieldwork was funded by Houston Zoo Inc. and conducted under SEMARNAT permit Oficio Núm. SGPA/DGVS/01085/07. Project title "Distribucion y abundancia de los reptiles y anfibios del Estado de Tamaulipas, Mexico."

FIG. 1. Record size *Tantilla rubra* from the border of the Jaumave and Victoria municipalities, Tamaulipas, Mexico.

***THAMNOPHIS ATRATUS HYDROPHILUS* (Oregon Gartersnake). DIET.** *Thamnophis atratus hydrophilus* inhabits sunlit streams and rivers of southwestern Oregon and northwestern California where its primary prey are small fish and amphibians. This species, like most aquatic snakes, exhibits distinct ontogenetic habitat and diet shifts. Neonate and small juvenile snakes are primarily sit-and-wait foragers that prey extensively on tadpoles, particularly those of *Rana boylii* (Foothill Yellow-legged Frog). Larger juvenile and adult snakes are active foragers and the proportion of fish in the diet and mean prey size increase with body size (Lind and Welsh 1994. Anim. Behav. 48:1261–1273). The most common fish reported in diets of *T. a. hydrophilus* are juvenile salmonids (genus *Oncorhynchus*), but they are also known to consume sculpins (genus *Cottus*; Brown et al. 1995. Reptiles of Washington and Oregon. Seattle Audubon Society, Washington. 176 pp.) and sculpin eggs (Bettaso et al. 2007. Herpetol. Rev. 38:212–213), and giant salamanders (*Dicamptodon tenebrosus*; Lind and Welsh 1990. J. Herpetol. 24:104–106; Lind and Welsh 1994, *op. cit.*). Here we present an observation of neonate *T. a. hydrophilus* preying on ammocoete larvae of *Entosphenus tridentatus* (Pacific Lamprey).

This observation took place at approximately 1300 h, on 3 September 2007, along the lower Klamath River, California, USA (41.5794°N, 123.5303°W; datum WGS84). We observed numerous neonate and juvenile *T. a. hydrophilus* basking and foraging along the river margin in areas dominated by exposed cobbles and small boulders interspersed among numerous alcoves and shallow side pools that contained extensive patches of fine sediment. One of us (ERP) captured a small *T. a. hydrophilus* (SVL = 188 mm) and while handling it, it regurgitated two recently ingested *E. tridentatus* ammocoetes measuring 54 and 61 mm total length. Gentle palpation of the upper digestive tract revealed that these were the only prey items in the snake's stomach. This observation is the first report of snake predation on lamprey ammocoetes, which are filter-feeders that reside in burrows in fine sediment (Moyle 2002. Inland Fishes of California. Univ. California Press, Berkeley. 502 pp.) and should, therefore, be highly cryptic to ambush predators such as juvenile garter snakes. It also suggests that garter snake foraging behavior and diet breadth may differ between large rivers and high gradient mountain streams, where much of the previous research on this species has been conducted (e.g., Lind and Welsh 1994, *op. cit.*).

MICHAEL S. PARKER (e-mail: parker@sou.edu) and **EMMA ROSE PARKER,** Department of Biology, Southern Oregon University, 1250 Siskiyou Blvd., Ashland, Oregon 97520, USA.

***THAMNOPHIS BRACHYSTOMA* (Short-headed Gartersnake). COLORATION.** The coloration of *Thamnophis brachystoma* typically consists of a background of olive to olive-brown, with a beige to yellowish vertebral stripe and two dull buff lateral stripes (Hulse et al. 2001. Amphibians and Reptiles in Pennsylvania and the Northeast. Cornell Univ. Press, Ithaca, New York. xii + 419 pp.). Schaefer (1972. Herpetol. Rev. 45:168) reported a

FIG. 1. Hypomelanistic *Thamnophis brachystoma* from Erie Co., Pennsylvania, USA.

leucistic specimen from McKean Co., Pennsylvania, USA. I know of no other color anomalies reported for *T. brachystoma*. Herein I report an instance of hypomelanism in this species.

On 4 September 2009, I found a neonate male *T. brachystoma* with a pale dorsal color under a piece of bark in an extralimital population in Springfield Township, Erie Co., Pennsylvania, USA (Fig. 1). The ground color was light beige and lateral stripes were not discernible. A lighter vertebral stripe was present, but only slightly contrasting with the lateral ground color. Small amounts of dark pigment occurred on the scales on either side of the vertebral stripe, corresponding to the dark border that is typically present in normally colored specimens. A pair of oblong black spots occurred just behind the parietal scales where the dark border is ordinarily thickened at the anterior terminus of the vertebral stripe. The seam between the parietal scales was thinly bordered with black, but the parietal spots usually present were not visible. The ventral color was the normal greenish gray, and the eye color appeared normal. The specimen has been maintained alive since capture, and after more than a year its overall color has darkened somewhat, but is still much lighter than is typical. Nine additional neonates were found at the site on the date of the observation, all showing normal coloration. The specimen (TREC R-00058) is being maintained at the Natural History Museum of the Tom Ridge Environmental Center at Presque Isle State Park, where it will be deposited upon its death.

MARK LETHABY, Natural History Museum of the Tom Ridge Environmental Center at Presque Isle State Park, 301 Peninsula Drive, Erie, Pennsylvania 16505, USA; e-mail: mlethaby@verizon.net.

TRIMORPHODON VILKINSONII **(Texas Lyresnake). MATING.** Information on the timing of breeding in species of *Trimorphodon* is scarce (Degenhardt et al. 1996. Amphibians and Reptiles of New Mexico. Univ. New Mexico Press, Albuquerque. 431 pp; Werler and Dixon 2000. Texas Snakes, Identification, Distribution, and Natural History. Univ. Texas Press, Austin. 519 pp.). At 2240 h on 16 April 2006, one of us (CN) was driving on County Road DO 12 west of Las Cruces, New Mexico, located on the bajada of the Sierra de Las Uvas mountain range (32.48538°N, 107.12330°W; datum: NAD83/WGS84; elev. 1537 m). The moon was waning gibbous with ~91% of the moon's visible disk illuminated. Air temperature was 18.0°C with ~ 24–40 km/h gusts of wind. An object seen earlier on the road and ignored was investigated several minutes later and found to be an adult pair of breeding *T. vilkinsonii*, the female having just been run over. At this point, the male, who was still entwined with the female, became disturbed and began to move off of the road. He was photographed and released. The female was deposited in the Museum of Southwestern Biology (MSB 75692). In Arizona populations of *T. lambda*, spermiogenic males were found in spring, summer, and fall, and females with enlarged follicles were found in May (Goldberg 1995. Southwest. Nat. 40:334–335). To our knowledge this represents the first documented date of copulation for wild *T. vilkinsonii*.

IAN W. MURRAY, MSC03 2020, Department of Biology, 1 University of New Mexico, Albuquerque, New Mexico 87131-0001, USA (e-mail: imurray@unm.edu); **CHRISTOPHER NEWSOM,** 5519 Amistad Rd. NE, Albuquerque, New Mexico 87111-1549, USA (e-mail: herpsofnm@comcast.net).

TROPIDODIPSAS PHILIPPII **(Philippi's Snail-eating Snake). ARBOREALITY.** *Tropidodipsas philippii* is a small, thin, snake species that has several morphological characteristics typically associated with arboreal habitat use such as protruding eyes, slight lateral compression of the body, and a relatively long tail. These characteristics, along with documented arboreality in closely related species, have led some authors to speculate that *T. philippii* is arboreal to at least some degree (Kofron 1987. J. Herpetol. 21:210–225; Scott 1967. Copeia 1967:280–287). However, no data exist to confirm this speculation.

Here we present the first documented case of arboreality in *T. philippii*. On 3 July 2008, between 0440–0520 h, during a herpetofaunal survey near Hwy 200 between La Placita and Maruata, Michoacán, México (18.48627°N, 103.54229°W, datum WGS84; elev. 126 m), we encountered a male *T. philippii* (SVL = 156 mm; total length = 207 mm) resting on a thin, arching dead stick ca. 20 cm above the ground (Fig. 1). Specimen identification was verified by E. N. Smith. A photographic voucher of this behavior is deposited in the University of Texas at Arlington Digital Image Collection (UTADC 6245). The specimen is deposited at the Amphibian and Reptile Diversity Research Center, University of Texas at Arlington (UTA R-58836).

PHOTO BY C. M. SHEEHY III

FIG. 1. *Tropidodipsas philippii* (UTA R-58836) in Michoacán, México, *in situ*, exhibiting arboreal behavior and possibly ambush posture.

Of particular interest is the position of the snake along the stick (Fig. 1). It was motionless and oriented head-down in a position similar to that often described as ambush posture for some arboreal snake species (e.g., *Corallus* spp., Henderson 2002. Neotropical Treeboas. Krieger Publ. Co., Malabar, Florida. 197 pp.). The snake was found after several hours of rain beside a dry riverbed and we suspect that it was using the stick perch as a vantage point from which to scan for snails and slugs moving in the damp leaf litter below. Preliminary data from a feeding behavior study led by CMS support this hypothesis in that captive *T. philippii* often use visual cues to initially locate and follow molluscan prey.

We thank J. A. Campbell for assistance, and G. N. Weatherman for assistance with field work. The National Science Foundation (DEB-0613802) provided financial support.

COLEMAN M. SHEEHY III (e-mail: cmsheehy@uta.edu), **JEFFREY W. STREICHER, CHRISTIAN L. COX,** and **JACOBO REYES-VELASCO**, Amphibian and Reptile Diversity Research Center, Department of Biology, University of Texas at Arlington, Arlington, Texas 76019, USA.

***TROPIDONOPHIS DORIAE* (Barred Keelback). ENDOPARASITES.** *Tropidonophis doriae* is known from Indonesia (Irian, Java, Aru Islands) and Papua New Guinea (Malnate and Underwood 1988. Proc. Acad. Nat. Sci. Philadelphia 140:59–201). It is a terrestrial, nocturnal predator that eats frogs and fish (Malnate and Underwood, *op. cit*). To our knowledge there are no reports of helminths for *T. doriae*. The purpose of this note is to establish an initial helminth list for *T. doriae*. Two *T. doriae* from the herpetology collection of the Bishop Museum (BPBM), Honolulu, HI, USA each had nematodes protruding from a slit in their body walls (BPBM 31526, SVL = 254 mm; BPBM 31527, SVL = 327 mm). Both snakes were collected on 3 April 2007 in Madang Province, Wanang, Papua New Guinea (5.232118°S, 145.18068°E; datum: WGS84; elev. 600 m). Nematodes were removed, cleared in glycerol, placed on glass slides, coverslipped, studied under a compound microscope and identified as *Tanqua anomala* (eight from BPBM 31526) and (six from BPBM 31527). Voucher helminths were deposited in the United States National Parasite Collection (USNPC), Beltsville, Maryland, USA as USNPC (103501) and the Bishop Museum (BPBM) as (H423). *Tanqua anomala* is common in snakes from southeast and southern Asia (Baker 1987. Occas. Pap. Mem. Univ. Newfoundland 11:1–327; Sood 1999. Reptilian Nematodes from South Asia, International Book Distributors, Dehra Dun, India. 299 pp.). There is a record of a larval *T. anomala* in *Hoplobatrachus tigerinus* (= *Rana tigrina*) in Baker (*op. cit*). As *T. doriae* feeds on frogs, frogs may act as paratenic (= transport hosts) for *T. anomala*. *Tanqua anomala* in *T. doriae* is a new host record. Papua New Guinea is a new locality record.

We thank Pumehana Imada (IBPBM) for facilitating our examination of *T. doriae*.

***XENODON NEUWIEDII* (False Lancehead). DIET.** The dipsadid snake *Xenodon neuwiedii* has a diet composed predominantly of anurans, especially those in the genus *Rhinella* (Marques and Sazima 2004. *In* Marques and Duleba [eds.], Estação Ccológica Juréia-Itatins: Ambiente Físico, Flora e Fauna, pp. 257–277. Holos, Ribeirão Preto; Sazima and Haddad 1992. *In* Morellato [ed.], História Natural da Serra do Japi: Ecologia e Preservação de uma Área Florestal no Sudeste do Brasil, pp. 212–236. FAPESP, Campinas). However, anurans belonging to other families (Hylidae, Leptodactylidae, and Cyclorhamphidae) and even lizards (*Enyalius* sp.) are occasionally consumed (Hartmann et al. 2009. Biota Neotrop. 9:173–184; Marques and Sazima, *op. cit.*). *Rhinella abei* is a frog distributed in the southern Atlantic Rainforest from Paraná state to southern Santa Catarina state and northern areas of Rio Grande do Sul state, Brazil (Baldissera Jr. et al. 2004. Arq. Mus. Nac., Rio de Janeiro 62[3]:255–282). Here we report the predation of the frog *R. abei* by the snake *X. neuwiedii*.

PHOTO BY M. WACHLEVSKI

FIG. 1. An adult female *Xenodon neuwiedii* found preying on a *Rhinella abei* in the Parque Estadual da Serra do Tabuleiro, Brazil.

On 16 January 2009, in the Parque Estadual da Serra do Tabuleiro, Santo Amaro da Imperatriz municipality, Santa Catarina state, Brazil (27.7427°S, 48.8075°W, datum: SAD 69), an adult female *X. neuwiedii* (SVL = 489 mm; tail length = 113 mm; 59.5 g), was found at 1015 h on leaf litter in an area of dense ombrophilous forest ingesting an adult *R. abei* (SVL = 69.1 mm; 26.2 g; 44% of the snake's mass). The frog was being ingested headfirst, ventral side up, and was still alive (Fig. 1). Manipulation of the snake resulted in the release of the prey, which presented deep wounds in the abdominal region. Batracophagy seems to be the most frequent feeding habit of *Xenodon* (Marques et al. 2001. Serpentes da Mata Atlântica. Guia Ilustrado para a Serra do Mar. Ribeirão Preto, Editora Holos. 184 pp.) and some species have specialized skulls and dentition, facilitating the capture and ingestion of frogs (Kardong 1979. Evolution 33:433–443). The wounds we observed are evidence of the functionality of *X. neuwiedii*'s enlarged posterior teeth, which allow perforation of the prey and the consequent evacuation of air, which is accumulated in the toad's body for defense (Amaral 1978. Serpentes do Brasil, Iconografia Colorida, 2ª edição. Melhoramentos/EDUSP, São Paulo. 247 pp.).

The Chinese Alligator is one of those rare technical books that is a really good read. As George Schaller so poignantly points out in his foreword, "too many plants and animals spiral toward extinction quietly and without someone to mourn their fate." Thorbjarnarson and Wang fulfil the imperative, as Schaller puts it "...that with meticulous science, tenacity, cultural awareness and hope, any species can be offered a future." And few species on earth could be held up as such a startling example of survival against all odds as the Chinese Alligator.

Chapter 1, 'The Earth Dragon,' is a quick outline of John T.'s first visits to China in pursuit of the last remaining wild alligators. In 1998 he was stunned that the alligator's wild habitat in Anhui Province was virtually gone; previous reports by the Chinese authorities had painted a much rosier picture. Long, discouraging forays down narrow country roads, winding through a horizon to horizon agricultural landscape to find the last survivors, ended in a devastating car wreck with John suffering a broken femur and shoulder. The following year John and his Chinese/American team were elated to find a wild nest, one of the very few, and the reality of the situation starts to unravel. There were thousands of Chinese Alligators in captivity and perhaps 150 in the wild and it was disturbing that the lines between captive and wild animals were getting blurry, with development of large captive facilities taking precedence over consolidation of wild habitats.

Chapter 2 is an introduction to the world's crocodilians, their conservation and utilization and you couldn't ask for a better concise rendition. In contrast to the Chinese situation, the success story of the American Alligator, with 100s of thousands happily cruising the swamplands of the southeastern USA, is a truly remarkable 21st century crocodilian situation. Being the State emblem of Florida is certainly a help. The point is well made that with adequate protection in the 1960s the resilience of the alligator allowed it to rebound so vigorously that the species is an important economic resource and wetlands are thereby valued for sustaining this resource. But the Chinese situation is so very different: there is little or no alligator habitat left.

The book then takes us on an historical journey, starting with the evolutionary history of Chinese Alligators and unravelling the complex mystery of why only China and the USA have alligators. After a crash course in the cooling and heating of the earth and how it facilitated the odd distributions of plants and animals, we are told that "...the affinities between the flora and fauna of the eastern United States and eastern Asia are the result of what was in the early Tertiary, a widespread, temperate forest biome that spanned the two continents." Fossil records indicate a much wider distribution for the Chinese Alligator in prehistoric times and that the expansion of human populations was probably responsible for its extirpation from its northern range. The authors delve into what seems every possible reference to the alligator from 5,000 year old oracle bone inscriptions to the *I Ching*, creating a fascinating montage of how the 'earth dragon' was visualized and personified over the millennia. Accounts of the alligator's biology and behavior are quoted from classical texts going as far back as the 1500s, but it was a French customs officer and amateur naturalist stationed in Shanghai, A. A. Fauvel, who first described the Chinese Alligator to the world. His treatise *Alligators in China: Their History, Description and Identification* was published in 1879 and was a compilation of everything that was then known about the species.

After the Giant Panda, the dragon is the first animal we think of in the Chinese context. The authors trace dragon myths worldwide and for China make the very obvious link to the alligator, an admittedly smallish dragon at only seven feet. There are few creatures that are as pervasive in world mythology as the numberless morphs of the dragon. Humans are intensely fascinated by the horror of being killed and eaten by a predatory animal and the authors narrate an incident that happened while they were writing the book. An American doctor was pulled from a canoe and killed by a crocodile in Botswana and the news sent shock waves through the world media. But if he had drowned or been killed in a car accident the press would have paid little notice.

The next chapter, 'A Dragon's Life' is literally a monograph of the ecology and behavior of this cryptic and perhaps least known (*Tomistoma* and Dwarf Caiman are also contenders) of crocodilians. It has a lot in common with American Alligators,

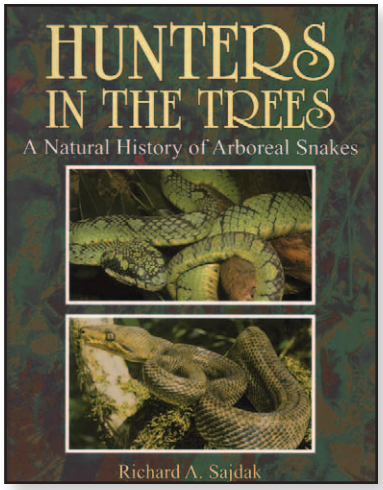
but, perhaps partly because of persecution, it is not the conspicuous animal its cousin has become. A prodigious tunneler, the Chinese Alligator has hard winters to put up with, floods, and, in most areas, a less than supportive human populace. Indeed as the authors say, it is their ability to remain hidden most of the time in underground burrows that has enabled them to survive in the modern agricultural landscape. Here one will find nest size, clutch size, and literally everything that has been found out about these beasts from Chinese biologists studying them in the field and in captivity and American biologists at the Bronx Zoo and Rockefeller Wildlife Refuge, where they were bred for the first time outside of China.

Next is a chapter on the 'Dragon's Demise,' a chronicle of what happened to what was once a wide-ranging crocodilian and to the Yangtze River, the wetlands of which were its primary home. In many ways this history typifies what has happened (is happening) in many parts of the world: rivers being raped, plundered, dammed, diverted, and emptied of water and life for the sake of agriculture to feed burgeoning populations of humans. The recent extinction of the Chinese River Dolphin in the Yangtze is a tragic and ominous portent of what is facing the other major wetland life form, the alligator. In the 1930s it survived "only in the great swampy lakes lying to the south of the Lower Yangtze" in Anhui, Jiangsu, and Zhejiang provinces. By the 1970s it was found only in a small region in Anhui and Zhejiang provinces.

The Chinese authorities have long been aware of the demise of the alligator and the initial response was for the Anhui Forestry Bureau to set up the National Chinese Alligator Reserve, a 433 km^2 area, later reduced to 308 km^2, with an estimated total population of 150 wild alligators. The chapter on habitat and population status graphically describes how the alligator became more and more confined to a few pockets as the human population increased by over 200% since the 1930s. In the past alligators were revered, but local beliefs that alligators make it rain worked against them in recent years when floods were blamed on them! But nothing was so devastating to the alligator as the spread of human settlements and agriculture into virtually every last wetland they inhabited in China. In the early 1980s the Anhui Research Center for Chinese Alligator Reproduction was established as a captive breeding facility and stocked with animals caught from the wild and for a long time every nest that was found in the wild was taken to the Center for hatching and rearing. Releases were made but follow up and monitoring was minimal so the results were questionable.

The final chapter in the book is the longest, 'The Future of the Alligator in China' and provides a comprehensive look at China's efforts so far and the authors' vision of what efforts should be made in future. Basically the authors bemoan the fact that the Chinese authorities seem quite complacent as long as there are plenty of captive animals (about 10,000 today), but precious little effort was being spent on securing wild habitat. This resonates strongly with Indian croc biologists as we watch the steady demise of the Critically Endangered Gharial, primarily due to loss of its riverine habitat. As in China, government schemes for egg collection and captive breeding have now become the visible 'feel-good' face of conservation efforts while habitats are distorted beyond ecological utility and river people are further alienated from conservation goals.

Altogether an excellent and important read (if I had one quibble it would be for more photos and in color), *The Chinese Alligator* is a rare combination of science, common sense, and a passionate plea to look carefully at what we have left in the world and to nurture the last dragons. In his foreword, George Schaller writes: "*The Chinese Alligator* shows with detail, insight and vision that an attempt must be made to save species no matter how complex the problems." The authors are optimistic: "Despite its present dilemma, the Chinese alligator is a species with a potentially promising, perhaps even dramatically successful, future. It is with this hope that we have written this book."



As I wrote this, I envisaged John T., dressed in his trademark Hawaiian shirt, smoking a Cuban cigar quietly holding forth about salties in Burma, gharial in India, Cuban crocs in the Zapata swamp, or Orinocos in Venezuala with other obsessed members of the croc biologist fraternity. A mosquito felled this titan and he is sorely missed across the planet.

Hunters in the Trees: A Natural History of Arboreal Snakes

By Richard A. Sajdak. 2010. Krieger Publishing Co., Malabar, Florida (www.krieger-publishing.com). 192 pp. Hardcover. US $64.00. ISBN 978-1-57524-303-0.

ALEX FIGUEROA
Department of Biological Sciences, University of New Orleans
2000 Lakeshore Drive, New Orleans, Louisiana 70148, USA
e-mail: afigueroa21@gmail.com

There are approximately 3309 named species of snakes, with arboreal forms accounting for more than 500 of these. Arboreal snakes do not represent a monophyletic lineage but rather a collection of species with arboreal habits, distributed primarily within the families Boidae, Colubridae, Elapidae, Pythonidae, Ungaliophiidae, and Viperidae. No strict definition exists for what constitutes an arboreal snake, but given that most snakes have the ability to ascend vegetation, and do so for various reasons (i.e., basking, sleeping, foraging, and predator avoidance), 'true' arboreal snakes are best considered those that spend the majority of their time, and carry out the bulk of their activity, in arboreal habitats.

Prior to this book, the only comprehensive examination of the biology of arboreal snakes was Lillywhite and Henderson's (1993) review chapter in *Snakes: Ecology and Behavior*. There exist a number of inherent difficulties associated with observing and studying arboreal snakes, thus hard data on the biology of arboreal snakes are scarce. Nonetheless, there is enduring interest in these animals as reflected in the 427 references cited by Sajdak, many of which will be of use to anyone studying not only snakes, but arboreal organisms in general.

The book contains 13 chapters, the first five of which review general snake biology as it relates to arboreal species. Chapter 1 serves as a fascinating introduction to the features associated with arboreality in snakes. It outlines the morphological specializations for an arboreal existence, emphasizes convergence and the repeated evolution of arboreality among distantly related species, and considers the global distribution of arboreal snakes. Convergence in morphology, ecology, and behavior are hallmarks of arboreal snake taxa, and it is convergence that is the main organizing principle used by Sajdak to arrange this book. Nonetheless, few studies have empirically tested convergence or measured morphological adaptations in arboreal snakes (e.g., Henderson and Binder 1980; Martins et al. 2008; Pizzatto et al. 2007).

The subsequent four chapters continue with conventional information pertaining to coloration and its function, locomotor styles and the functional demands associated with moving in a three dimensional environment, and diet. Of particular interest is Sajdak's discussion of the ideas of arboreal ecomorphs, niche partitioning, and community structure. In these chapters, readers gain insight into why the snake body plan is advantageous for an arboreal lifestyle and what changes occurred in morphology in order for snakes to become successful tree hunters. Sajdak does an excellent job in summarizing the literature in these chapters and clarifying much of the physics and physiology associated with arboreal habits as discussed in Lillywhite and Henderson (1993), making the book easily accessible to a wide audience.

The remaining eight chapters are dedicated to the diversity of arboreal snakes. Here, Sajdak provides readers with an appreciation for the number of times arboreality has evolved in snakes, the changes to morphology and ecology that accompanied these evolutionary shifts, and the role of arboreal prey types in allowing multiple snake lineages to radiate and flourish in the trees. These chapters are organized by snake family or by similarities in morphology and prey type (guilds). However, I find this approach somewhat subjective and exclusive. For instance, individual chapters are devoted to snakes specializing on frogs, birds, mammals, and invertebrates. Lizards as prey are accounted for in Chapter 6, "The Snipers—Vine Snakes," making it seem as if only vine snakes feed on lizards, when they are, in fact, taken by a diversity of arboreal snakes. Likewise, the titles of other chapters such as Chapter 11, "The Night Shift—Boas and Pythons" or Chapter 12, "The Poisoners—Tree Vipers," are also somewhat misleading in suggesting that only boids and pythons are nocturnal and only vipers are venomous. In addition, although discussed in the chapter on vipers, I was expecting to read in Chapter 8 ("Birds and Snakes") about the extraordinary role birds played in shaping the morphology and driving the evolution of *Gloydius shedaoensis* and *Bothrops insularis* to an arboreal existence. Nonetheless, this treatment of the diversity of arboreal snakes is a fantastic overview of how creatures of fossorial ancestry evolved to overcome physical and environmental challenges and conquered the trees.

Certain chapters would have benefited from subheadings, as topics change unexpectedly between paragraphs, interrupting the flow of the book. But if the book suffers from anything, it is the deficiency of data for many arboreal species. As a result, a great deal of the information presented in the book is drawn from research on just a few well-studied taxa; in some cases, entire chapters are almost wholly dedicated to such species. This is, of course, a consequence of the state of arboreal snake research, not a fault of the author, and indeed, Sajdak does provide commentary on lesser known species and indicates areas where more research is critically needed.

The book concludes with two appendices and a section entitled "Chapter Notes and References." Appendix 1 is a comparison of color patterns between arboreal and terrestrial snakes compiled from five regional guides and Appendix 2 is a list of blind snake species found in arboreal situations detailing the locality along with the height and substrate on which the snakes were found. However, 15 of the 19 records are from only a single reference. These two appendices might have been better presented as tables within relevant chapters. "Notes and References" does not include any notes, but simply lists the references used by chapter.

Of course no book on snakes is complete without color images. In this regard, the book lacks separate photographic plates, but instead intersperses images of varying size throughout the text. Some of the photos could be of better quality, but for the most part, they are superb images obtained from several photographers showcasing various arboreal species from around the world, often illustrating feeding behavior, threat displays, or other aspects of natural history. Other images show "non-arboreal" snakes captured in arboreal situations. Photographs aside, however, the book includes only five figures and no tables. The first two figures are the most useful, comparing the distribution of arboreal snakes with the distribution of the world's forests, suggesting that arboreality in snakes is predominately a tropical phenomenon. Unfortunately, Figure 1 also has a blatant spelling error that is hard to overlook. The remaining figures are less illuminating, but useful nonetheless, and I would have liked to have seen them adequately cited within the text.

Hunters in the Trees is undeniably a valuable compendium on the biology of arboreal snakes and will serve as a useful reference for researchers or hobbyists, and an excellent introduction to these snakes for members of the general public interested in tropical natural history. Sajdak's decades of field experience, knowledge, and passion for snakes are evident in his clear and simple writing style and engaging narrative, and readers will also appreciate his personal touch of illustrating postage stamps of arboreal snakes at the end of each chapter.

Margarita, with an area of 1150 km², is Venezuela's largest island and its main tourist attraction (at least as measured by numbers of visitors). Despite a much less diverse herpetofauna than the Venezuelan mainland, and the near lack of endemics, Margarita and its satellite islands Coche and Cubagua still present an interesting introduction to the Neotropical herpetofauna, with five species of amphibians and 45 of reptiles. The herpetofauna of Margarita was treated extensively by Roze (1964) who mentioned four amphibians and 36 reptiles, and much later by Rivas et al. (2005), who added eight species to the previous list. But now, Gabriel Ugueto and Gilson Rivas present a new, improved, and more extensive treatment of the fauna in their new book.

The book starts with a foreword by Janis Roze, the former authority on Margarita herpetofauna (as well as on Venezuelan snakes), introducing the work of these two young Venezuelan herpetologists. A short acknowledgments section follows. An introduction briefly reviews the history of the discovery of Margarita and its satellite islands and the earlier work of herpetologists there. A "How to Use this Book" section explains the goals of the field guide and the categories of information supplied for each species. A more extensive chapter deals with the geography and habitats of the islands. This is followed by a brief geological history and a discussion of the zoogeography of the island, assigning all species to different categories: Widespread taxa, Caribbean coastal range taxa, Coastal arid lowland taxa, Cosmopolitan taxa, Amazonian taxa, Orinoco Basin taxa, and Lowland Guiana endemic taxa. It is curious that such a large island in the Caribbean does not harbor a higher number of endemics especially when compared with neighboring Trinidad and Tobago (see table 3 on page 47). To date only three reptiles are known to be endemic to Margarita: an undescribed species of *Gonatodes*, the recently described Gray-headed Whiptail *Cnemidophorus senectus* (Ugueto et al. 2009), and the Margarita Cribo (*Drymarchon margaritae*). *Scinax* aff. *x-signatus* may also be an undescribed species, but it remains to be better studied.

Margarita and Coche Islands are suffering from unrestrained touristic and urban development, affecting large areas of wilderness. As explained in the next section "Conservation," there are some attempts to conserve critical areas for important species and there are a few conserved areas, such as national parks and natural reserves on the islands.

A few species of amphibians and reptiles have been erroneously reported from the islands by previous authors or are of questionable presence. These include *Scinax ruber, Leptodactylus mystaceus, Crocodylus acutus, C. intermedius, Gonatodes ocellatus, Cnemidophorus lemniscatus, C. nigricolor*, and *Tupinambis teguixin*. All these cases are carefully explained by the authors.

Confirmed taxa are presented in a checklist of five species of amphibians and 45 reptiles known from Margarita, 12 reptiles from Coche and 13 from Cubagua. We take advantage of this review to add a few new localities for some species on Margarita and Coche. In a recent short casual visit by one of us (CLBA) to Coche Island, two previously unreported species were observed, the only amphibian known for the island, *Pleurodema brachyops*, and the expected but previously undocumented Gray-headed Whiptail, *Cnemidophorus senectus. Pleurodema brachyops* has also been known from the arid Punta de Piedras on Margarita for many years (OMLA, pers. obs.), but there are no vouchers. *Mabuya nigropunctata* is reported in the book only from one locality in Cerro Copey; it also has been observed in the little explored Cerro Tragaplata, in the northeast of Margarita. And finally, a dying specimen of *Dermochelys coriacea* arrived on the beach at Punta de Piedras in 1997 and was buried close to the Museo Oceanologico Hermano Benigno Roman. This constitutes the first report of the species on the southern versant of Margarita.

Before the species accounts there is a quite complete introduction to amphibians, and another to anurans (the only amphibians known to the islands) specifically, with a useful and easy to use dichotomous key to the family level. There are also introductions to each family, and if necessary (in families with more than one represented species), another key to the species level. The species accounts start with the five amphibians known from the islands, all widespread species on the mainland. Each account has a comprehensive identification section, followed by sections on habitat, natural history, diet, voice, reproduction, distribution, and remarks (when necessary). There is a distribution map and one or more photographs for each species. The reptile account part is also very comprehensive, with all the same sections as for amphibians except for "voice" and the addition of a "venom" section for the three venomous species of the islands. Between the amphibian and reptile sections are 12 plates illustrating all species from the islands except the Margarita Cribo, which has not been seen alive in recent times.

At the end of the reptile chapter, there is a section about species of possible occurrence, not yet confirmed, but with high probabilities of occurring on the islands. These include *Eleutherodactylus johnstonei* (introduced in Venezuela), and reptiles known from the adjacent mainland: *Mabuya falconsensis, Amphisbaena alba, Chironius spixi, Tantilla melanocephala, Clelia clelia, Ninia atrata,* and *Thamnodynastes ramonriveroi.*

The book closes with a chapter on venomous snakebite on these islands, and an appendix of examined material. The Literature Cited is comprehensive.

This is the first serious attempt to gather all the information about amphibians and reptiles of these islands in book form. Venezuela is one of the ten most biodiverse countries on Earth, with nearly 350 species of amphibians and 400 of reptiles. However, relatively little has been published about its herpetofauna and only a few attempts have been made to gather data, and then usually in a taxon-specific way (e.g., Roze 1966, Lancini 1979, Lancini and Kornacker 1989 for snakes; Pritchard and Trebbau 1984 and Rueda et al. 2007 for chelonians; Medem 1983 and Rueda et al. 2007 for crocodiles; and nothing exhaustive for lizards or amphibians).

This book accomplishes two goals. First, to be a comprehensive statement about the entire herpetofauna of a particular region (the state of Nueva Esparta in Venezuela), and second, to provide as much data as possible about each species, not only on these islands, but wherever they occur on the mainland.

Apart from the high quality information, which is accurate and well written, the most striking part of this book are the delightful plates by Ugueto. Few extraordinary works (e.g., Duellman 1970, 1978) have plates as beautiful and inspiring as the ones in this book. The plates illustrate all species on the islands except for the mysterious Margarita Cribo, and each one is both an artistic delight and a very accurate taxonomic aid. All the rest of the schematic drawings in the book were also executed by Ugueto, revealing his amazing skills as artist and designer, as well as a herpetologist.

The photos in the book also illustrate nearly all the species on the islands (except for *Scinax* aff. *x-signatus* and again the Margarita Cribo, and *Mastigodryas amarali* is represented only as a preserved specimen) and almost all the possible species (except *Clelia clelia* and *Thamnodynastes ramonriveroi*). All pictures are of good to very good quality. Not all, however, represent island specimens as would be desirable, although this is understandably difficult to achieve. Some habitat pictures (e.g., figure 5 on p. 19) are completely meaningless, and some are repetitive (e.g., figures 11 and 12 on p. 24). The pictures showing *Amazona barbadensis* and *Cebus apella margaritae* are not of good quality, seem irrelevant, and should have been excluded.

Otherwise, aside from a few typographical errors (we counted fewer than 10), a few considerations should be taken into count for the next edition of this book. First, we know of no place on Margarita with an annual precipitation of 1100 mm, as stated on page 15; the maximum recorded is 900 mm (Hoyos 1985). If there is such a place, it would be important to provide a specific reference. The correct name corresponding to the acronym MHNLS is Museo de Historia Natural La Salle, not as on pages 14 and 50, Museo de la Sociedad de Ciencias Naturales La Salle. It is unclear if the habitat map shown on page 20 is original or if it is taken from some source, in which case this should be referenced. In the "habitat" section of *Gymnophtalmus* sp. aff. *speciosus*, the text indicates that the species is "occasionally" found in and around human habitation. One of us (OMLA) used to live in Margarita for prolonged periods, and can verify that *Gymnophtalmus* is actually a very common lizard that is often found in backyards and gardens. On figure 85 (page 213), on an otherwise beautiful and useful schematic figure of squamation, the supraoculars appear twice. Figure 88 showing *Epictia goudotti* cross references figure 77, but should read figure 87. The lack of a life photo of one of the most characteristic species of snakes on Margarita, *Mastigodryas amarali*, should also be rectified. It is not a rare species, and we are aware of available photographs. Figure 121, showing a rattle of a preserved specimen of *Crotalus durissus cumanensis*, should be accompanied by the collection number. The Red-footed Tortoise is referred to *Geochelone* in the book, but is properly referred to *Chelonoidis*, as are the rest of the Neotropical tortoises (Le et al. 2006). The Lesser Antillean Coqui, *Eleutherodactylus johnstonei*, is treated as a species of possible occurrence. OMLA can verify that it is already established in gardens of Pampatar and Porlamar. On page 322, treating *Amphisbaena alba*, the authors commit a *lapsus* referring the species to an order within Squamata in the text, while in the heading of the species account it is correctly allocated to the Suborder Amphisbaenia. In relation to this species, Gilson Rivas and Oscar Lasso-Alcalá have recently received (in January 2011) from Luis Bermudez (Ministerio del Ambiente de Venezuela) two specimens from "Salamanca" and "La Asunción," that confirm its presence on the island. We found also a couple of references not quoted in the Literature section: Fry et al. (2006) on page 110, and Narvaes and Rodrigues (2009) on pages 67–68. The last thing to mention is that a Spanish edition of this book would be very useful to Venezuelan students who do not speak English. We understand that this is probably an editorial decision, but a bilingual book would be very useful. All of these issues can easily be updated or corrected in a new edition, and in no way diminish the significance and utility of this book.

Venezuela (and especially Nueva Esparta state) can be happy and proud that two young Venezuelans took so much time and combined their efforts to bring together so much information in such a beautiful book. This volume is not only a must for the libraries of all herpetologists interested in the Neotropics, but also for anyone who enjoys and appreciates superb herpetological artwork. Indeed, we predict that the plates will set a new standard modern herpetological works.

Common Kingsnakes—A Natural History of *Lampropeltis getula*

By Brian Hubbs. 2009. Tricolor Books, Tempe, Arizona (tricolor_books@yahoo.com). Softcover. xxiv + 412 pp. US $60.00. ISBN 978-0-9754641-0-6.

Baton Rouge, Louisiana 70898-9000, USA
e-mail: jboundy@wlf.la.gov

As Douglas Rossman retired from more than thirty years of teaching herpetology, I asked him how many of his students developed an interest in snakes from taking his course. His gaze turned contemplative, and after a moment, as if to emphasize what he was about to say, held up a finger. "One," he stated. He had confirmed my own observation that those who pursue herpetology as a career, avocation, or hobby usually develop that interest in childhood, often from the encounter with some fascinating reptile, whether in the wild or a pet shop. The youthful enthusiasm wanes in many, leaving drawers of decades-old field notes and fading photographs. There are likely hundreds, perhaps thousands of such unheralded, potential contributors to the field. On the other hand, many people maintain an uncurbed passion for reptiles, outside of the realm of academia. Sadly, the wealth of information accumulated by these individuals is rarely manifested outside of a circle of close associates, and is usually lost within a generation. What if just one of these nonprofessionals published their observations? Would they present a valuable contribution to herpetology? With *Common Kingsnakes* Brian Hubbs offers us an example.

Hubbs' first words in the Preface ostentatiously get right to the point: "This is the most comprehensive look at the species, *Lampropeltis getula*, the story of Common Kingsnakes, a synthesis of accumulated experiences and data about their lives and surroundings. If that's what you were looking for you've come to the right place…" With those sentences the reviewer's red pen began to tremble in grim, yet reluctant anticipation. I labored through the Introduction and first two chapters ("Discovering Common Kingsnakes" and "An Overview"), spending as much time critiquing as reading. The nineteenth page is written "ixx" instead of "xix," kingsnake musk is said to be excreted from the anal opening, and the loreals may be fused with the supraoculars (perhaps preoculars was intended). There are strange statements: "All Common Kingsnakes share…habitat preference," "habitat preferences may differ between subspecies," "The morphology of those snakes is extensive," "Like many kingsnakes, most herpetologists…" There are hackle-raising terms: "cold-blooded," "Water Moccasin," and brain-stabbing phrases: "… wake up from hibernation," "Most criteria is dorsally-related…," …"active during crepuscular times." One could quibble page after page about editing, sourceless statements, and mal-interpretation of data to the point of frustrated anger. But after some hours it occurred to me that I could drop the pen and enjoy the book, which I did.

As the writer's cramp eased, I got used to Hubbs' style, and each page became a welcome turn. I found that ten chapters follow the introductory material, each devoted to eight taxa (those usually recognized prior to Pyron and Burbrink 2009), with brief chapters on the Isla Santa Catalina and Outer Banks populations. Each chapter contains a block of photographs depicting the range of variation of each subspecies, as well as habitats. The block for *L. g. californiae* contains 143 color photographs, that for *L. g. floridana* has 30. The blocks for *L. g. splendida* and *L. g. sticticeps* are inexplicably black-and-white; without a second copy of the book for comparison, I cannot say whether this is an anomaly. For each taxon Hubbs provides sections on Description, Discovery and Name History (nomenclature), Scutellation (typically from Blaney 1977), Size, Pattern and Coloration, Similar Species, Range, Habitat, Prey, Behavior, Emergence, General Activity, Breeding and Reproduction, Later Activity, and Abundance. The chapter on *L. g. californiae* is exceptional (114 pages), with extensive details regarding 72 natural pattern variants. Each variant here, as well as for the other taxa, is described and mapped, and most are illustrated with excellent photographs. The chapter on the Florida Kingsnake is exemplary, beginning with a fun story of Hubbs' childhood meeting with Ross Allen, and the events leading to his first *floridana* capture. The remainder of the chapter presents the biology of the taxon based on the author's extensive field work, cited publications, and numerous quotes from his correspondence with biologists and commercial collectors, old-timers and graduate students who know *floridana* firsthand. He finishes the chapter with a timely discussion of kingsnake declines in Florida.

Chapter 13, "Kingsnake Collecting and Wildlife Management," is a terrific essay that presents the philosophy and history of snake collecting, and chronicles the imposition and effect of laws on snake populations, public perceptions, and hobbyists. Hubbs presents the issues of snake collection from the sides of the collector, the neutral academic, and those who enforce wildlife laws. He backs his opinions with logical and convincing observations, which make his conclusions circumspect in nature. In contrast, Chapter 14, "How to Search for Common

Kingsnakes," seems hastily patched together. The chapter begins with the author's reminiscences of a favorite collecting site, followed with brief coverage of the "where, what, and how" of locating kingsnakes (his admonition to learn local game laws is an important point). There are four pages on how to set up a board line—a search method that Hubbs praises throughout the book. Hubbs recommends spraying the underside of cover boards with female kingsnake musk, but does not tell us whether he has tried this, or if it makes any difference to capture rate. "Road hunting" is dangerously facile. There is no mention of the skills required to drive the recommended "50–55" mph, "hang a U'" without rolling the vehicle or hit oncoming traffic, and get back to catch a snake that was beating it across the road 20 seconds ago. Hubbs recommends salvaging roadkills, but offers no guidance on methods of preservation or locating repositories. The recommendation to "start at dusk or whenever conditions are right" is exceptionally vague.

The book winds down with a chapter on Designer Morphs, another on Captive Husbandry, an appendix of breeders and snake-related organizations, a glossary, and list of references. The Designer Morphs chapter contains 41 color photographs of some spectacular oddities in colors and patterns. The "Jelly Brooks" resembles how I would imagine an ancestral *getula-triangulum* link might have looked.

Hubbs' anecdotes and stories are well-written, and of a style beyond the ordinary recounting of activities. He acquaints the reader with events and surroundings that may seem less than tangential to the story, but pertinent to particular situations: having time off after work to climb a hill to look under a fallen sign (many avocational herpetologists will relate to time-budgeting around jobs), rising at 0400 hours to beat the horrid Los Angeles-Orange County commuter traffic, standing in an Ozark stream to escape the oppressive midsummer heat, desperately trying to find a Black Kingsnake in Kentucky before darkness and/or the West Virginia state line thwarts his efforts, and the apprehension one feels when discovering another snake hunter in a favorite locale.

After my pummeled trudge through the edge-effect of the introductory sections, I found Hubbs the scientist—the exceptionally detailed accounts of the pattern morphs of *californiae*, the studied citations of researchers, and the thoughtful contemplation of the evidence capped by Hubbs's speculative hypotheses and summation of available data. That is the underlying theme of the book—after forty years of devotion to finding and studying kingsnakes, Hubbs has discovered for himself many of the integral theories of the natural world. He substituted the desiccating lecture halls of academia with the kingsnake in its environment. I realized that the labored presentation of what I considered common science was Hubbs writing as though he is sharing with the reader the process by which he discovered new concepts. He describes the variable abundance of snakes along roadways without using the terms population source and sink, and the habit of some snakes using the same cover over a period of years without the term site fidelity. He discusses at length how kingsnakes coil under plywood during cool temperatures, devoting an entire section to the topic of thermoregulation. He discovers that the striped morph of *californiae* is restricted to grasslands, and concludes that striping has a cryptic advantage in that habitat.

Throughout the book, Hubbs makes philosophical points. He notes that if people understood kingsnakes, they would appreciate and begin to understand the snake's environment, and with that appreciation will come conservation of their habitat. He believes that some snake researchers are ignorant of snake population sizes, and emphasizes his calculations of abundance to confirm his belief. He argues that laws that prohibit catching kingsnakes create a generation of hobbyists who never seek kingsnakes in the wild, and are oblivious to the effects of man on the snake's environment. He infuses the text with personal anecdotes, and quotes from others, both published and personal communications. It is clear that Hubbs has researched *L. getula,* solicited data from both snake enthusiasts and professional herpetologists, and pursued leads to discover as much as possible about kingsnakes in their environment. I was educated on a number of topics: female kingsnakes musk significantly more often than males; the designer-morph industry eliminated the market for wild-caught morphs; some snake species are most active on roads on windy nights (during atmospheric pressure changes); dorsal striping occurs in some *L. getula* from the Gulf Coast of Florida.

From a scientific vantage, there is one flaw to the book, which is the inconsistent sourcing of information. Hubbs frequently makes statements without reference, and it is often difficult to determine whether a statement is based upon something he read, heard from others, learned from his own observations, or is purely speculation (e.g., "It is believed that kingsnakes shed roughly 4 to 6 times a year in the wild"). Some that seem speculative are reasonable, though no evidence is provided as to how such a conclusion was reached (e.g., "In grasslands, sand hills and open woodland, the snake will simply hibernate underground, and its home territory will normally be much smaller than those that must seek specific hibernaculum"). Similarly, he makes frequent reference to "his data." Having observed over 2000 kingsnakes in the wild, it is disappointing that quantitative data are rarely presented. The "data" occasionally manifest themselves: ratios of color morphs in *californiae* at different sites, some counts with which he estimates the number of *L. getula* per acre in certain habitats, and dates of winter emergence. He also presents numerical data on body temperatures, monthly counts of observations, and clutch sizes as published by others. Relating to the eventual loss of data accumulated by amateurs, Hubbs found it difficult to find information from collectors of the 1950s and 60s on pattern morphs in coastal California and numbers of snakes encountered on desert roadways.

Hubbs is inventive when he can find no standardized terminology or metrics. He categorizes color pattern as class, type, phenotype, and morph. Each is a sub-category of the previous, except that phenotype and morph are "interchangeable," though morphs are more subtle variants. The definition of each term is found in four paragraphs on page 19, which are again pasted on pages 38–39. A list of 37 Morphs of *L. g. californiae* is found on page 49, and a list of 34 Aberrant Morphs is provided on page 56. In case the reader is confused, Hubbs explains that the term "aberrant" describes patterns that vary from typical patterns, and that there are aberrant morphs and aberrant snakes. He quantifies the terms "common" (3–9 snakes per acre) and "abundant" (over 10 snakes per acre). What if one should find an even 10 snakes per acre?

Hubbs has the enviable option of limitless space and verbiage. His book consists of heavy, high-gloss pages within covers of heavier paper. It is sturdy. The spine states *Common Kingsnakes* in no-nonsense, bold, block letters. No matter where it is on my shelves, I will immediately be able to find it. The text is composed of relatively small font size, though of a bold, block

type that allows easy reading. The hundreds of photographs and maps are perfectly produced in size (usually about 10 x 7 cm) in tones and colors that optimize detail. In physical aspect the book is extraordinary.

Hubbs summarizes the dilemma of amateurs in the study of herpetology as "...a lack of credibility. Amateur herpetologists are not usually taken seriously, or as a valuable source of information.... In our society, it doesn't seem to matter what you know; it's all about qualifications, perceptions, and how many are on your side." With *Common Kingsnakes*, Hubbs has demonstrated that he is a valuable source of information, knows a lot about his subject, and is qualified to be an authority. He has shown what can be produced where laws allow citizens to catch, keep, and study native species, as opposed to countries or states in which those practices are forbidden. So, has Hubbs, an avocational herpetologist, made a valuable contribution to science? Indisputably so: he provides a wealth of unpublished information that compliments what is already known about *L. getula*—information that would otherwise be lost. As he stated in his Introduction, anyone interested in the Common Kingsnake has, indeed, "come to the right place." *Common Kingsnakes* was written, produced, and published solely by Brian Hubbs. For that reason, the book is a creation and expression of just what its author wished rather than what the reader wishes it to be. It is beyond criticism—it is Brian Hubbs at his literary finest.

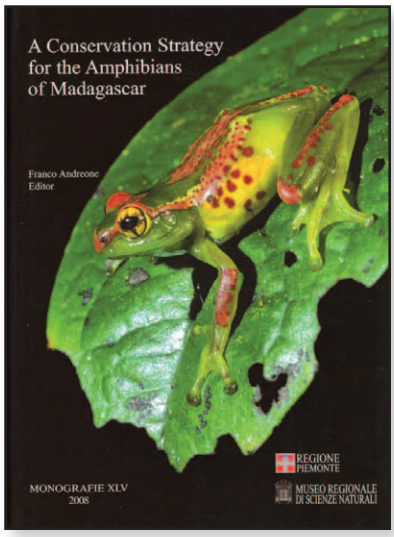
Pyron, R. A., and F. T. Burbrink. 2009. Systematics of the common kingsnake (*Lampropeltis getula:* Serpentes: Colubridae) and the burden of heritage in taxonomy. Zootaxa 2241:22–32.

PUBLICATIONS RECEIVED

A Guide to the Rattlesnakes of the United States

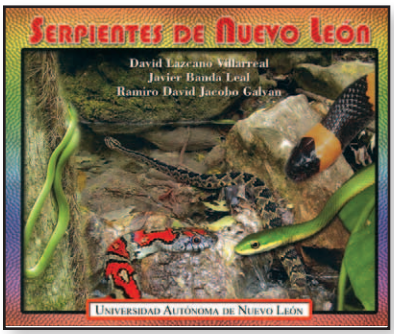


By Brian Hubbs and Brendan O'Connor. 2009. Tricolor Books, Tempe, Arizona (tricolor_books@yahoo.com). 96 pp. Softcover. US $20.00. ISBN 978-0-9754641-2-0.

This slim book is a nice introduction to U.S. species of rattlesnakes for persons who know little about them. General information about rattlesnakes (identification, venom, reproduction, legal protection, etc.) gives readers some necessary background. Brief accounts for 29 of 31 taxa (only subspecies of *Crotalus cerastes* are not accorded their own accounts) include color photographs, generalized range maps, and basic information about size, habitat, common names, and miscellaneous tidbits of interest ("trivia"). Color photographs (101 of them) are distributed throughout, and generally are of excellent quality; some of these depict particularly interesting behaviors (e.g., male combat in *Crotalus willardi*) as well as intraspecific variation. Herpetologists probably won't encounter much new information here, but will likely appreciate the large number of photographs, all of which look to have been taken in the field.

A Conservation Strategy for the Amphibians of Madagascar – Monografie XLV

Edited by Franco Andreone. 2008. Museo Regionale di Scienze Naturali, Torino (anna.grassini@regione.piemonte.it). Hardcover. 449 pp. 50,00 Euro (approximately US $72.00). ISBN 978-88-86041-72-0.



Madagascar is one of the most biotically rich areas of the world and one of the most imperiled. Its frog fauna is diverse and the number of species known continues to grow through the efforts of numerous active research groups working on the island. In addition to an introduction and a guest-authored preface, the book contains 27 chapters. Four of these are in French with English summaries; the rest are in English with French résumés. Many of the chapters are illustrated with color photos of frogs and their habitats, as well as field workers engaged in their research. Well known international herpetologists with established projects in Madagascar, including Miguel Vences, Frank Glaw, Christopher Raxworthy, and the editor, Franco Andreone, figure prominently among the authors, as do many researchers. This volume presents a diversity of topics broadly related to

amphibian conservation in Madagascar, including some taxon-focused contributions (e.g., *Mantidactylus* and *Mantella*) and others that are geographically circumscribed (e.g., the Isalo Massif, Menabe, and Andasibe). Other topics include captive breeding, resource management, global warming, and habitat modeling, and several chapters place the Madagascan situation into the context of the Global Amphibian Assessment. Of particular interest is the paper by Ché Weldon and colleagues that reports the apparent absence of the chytrid fungus *Batrachochytrium dendrobatidis* in Madagascar, a bright spot in a landscape that has seen tremendous declines in amphibian habitats. Chapters by Andreone and Vences et al. place the study of Malagasy frogs into historical perspective, demonstrating increasing trends in the publication of herpetofaunal conservation papers and in the participation of Malagasy researchers as authors. Although the conservation situation for amphibians in Madagascar remains precarious and is in constant flux, this book provides an excellent overview of the status of research, threats, and strategies as they stood at the time of publication. The book will be of value to anyone interested in the Malagasy herpetofauna, as well as to amphibian biologists and conservationists in general.

Serpientes de Nuevo León

By David Lazcano Villarreal, Javier Banda Leal, and Ramiro David Jacobo Galvan. 2010. Universidad Autónoma de Nuevo León, Monterrey, Nuevo León. 502 pp. Softcover. 500 pesos (approx. US $43.00). ISBN 978-607-433-528-6. [In Spanish]

The Mexican state of Nuevo León, home to the country's third largest metropolitan area and second most prosperous city (Monterrey), is situated in the northeastern part of the country in the northern foothills of the Sierra Madre Oriental. It borders the Mexican states of Coahuila, Tamaulipas, Zacatecas, and San Luis Potosí, and shares its northern border with the United States (Texas). The authors divide the state into three principal physiographic associations: Sierra Madre Oriental, Altiplanicie Mexicana (high elevation desert and near-desert regions west of the Sierra Madre), and Planicie Costera del Golfo (low elevation coastal plain). Each of these is further subdivided in an attempt to convey the complexity of this diverse, biotically rich region, and is accompanied by color photographs to illustrate various plant communities. Chapters cover such topics as evolutionary history of reptiles, snakes in captivity and scientific collections, and taxonomy. An illustrated key to the species of snakes in Nuevo León is provided. Individual species accounts (for 61 native and one introduced species) range from 4–8 pages and most are accompanied by good quality color photographs (though not all depict forms occurring in NL), as well as a color map outlining presumed range within the state. As is common with other recent regional works from Mexico, production quality is quite good. This book appears to be targeting a broad audience of amateur naturalists, students, as well as professionals looking for an attractive introduction to the snakes of the Nuevo León. A companion volume on the lizards of Nuevo León is in preparation by Lazcano and colleagues.

Herpetofauna de las Dunas de Viesca y Su Habitat

by J. Gamaliel Castañeda Gaytán, M. Cristina García de la Peña, and David Lazcano Villarreal. 2008. Universidad Autónoma de Nuevo León, Monterrey, Nuevo León. 154 pp. Softcover. 200 pesos (approx. US $17.00). ISBN not provided. [In Spanish]

The sand dunes near Viesca, Coahuila (located about 65 km SE of Torreón) are ecological islands within the broader Chihuahuan Desert landscape in northern México. Of particular interest to herpetologists is that these dunes are home to *Uma exsul* (Coahuila Fringe-toed Lizard), a species endemic to dune areas in southwestern Coahuila. This species is considered endangered because of anthropogenic changes to its fragile ecosystem. Brief and fairly general species accounts are provided for five species of amphibians and 13 reptiles, although the number for reptiles would undoubtedly be higher beyond the immediate environs of the dune areas. Each species account includes one or more color photographs of mostly fair quality. This section takes up less than 40 pages. The remainder of the book is devoted to a brief introduction, often with color photos, of predators and prey, plant species characteristic of the dunes, and habitat examples, concluding with a brief discussion of human impacts and conservation concerns.

ERRATUM

An incorrect address was given for Yehudah Werner ("Herpetology at a biogeographical junction: Research and teaching at the Hebrew University of Jersualem [Israel]", vol. 42, no. 2, pp. 150–159). Dr. Werner's current affiliations are:

INFORMATION FOR CONTRIBUTORS

Herpetological Review is a peer-reviewed quarterly that publishes, in English, articles and notes concerning the study of amphibians and reptiles, as well as book reviews, commentaries, regional and international herpetological society news, and letters from readers directed to the field of herpetology. Articles reporting the results of experimental research, descriptions of new taxa, or taxonomic revisions are not published in ***HR***, but should be submitted to the ***Journal of Herpetology*** (for information, please refer to: http://www.ssarherps.org/pages/JHinstr.php). To submit a manuscript to ***HR***, please consult the SSAR webpage at:

<http://www.ssarherps.org/pages/HRinfo.php>

REPRINTS AND PAGE PROOFS

Reprints of notes or articles published in ***HR*** may be ordered through EZReprints (EzReprint@odysseypress.com), an online reprint ordering system. Authors will receive email notification as the issue goes to press. Page proofs are sent electronically to authors of all articles, book reviews, and obituaries, but are not sent for natural history notes or geographic distribution notes. Proofs are sent as pdf files approximately 2–4 weeks prior to publication. Corresponding authors who are current members of SSAR will automatically receive free, screen-resolution pdf files of their articles or notes.

ADVERTISING

Herpetological Review accepts commercial advertising. Rates and copy information are available from the SSAR web page (http://www.ssarherps.org/pages/HRinfo.php).

Herpetological Review (ISSN: 0018-084X) is published quarterly (March, June, September, and December) by the Society for the Study of Amphibians and Reptiles at Central Michigan University, Department of Biology, 217 Brooks Hall, Mt. Pleasant, MI 48859, USA. Periodicals postage paid at Mt. Pleasant, MI 48859 and at additional mailing offices.

All rights reserved. No part of this periodical may be reproduced without written permission of the Editor, except that authors and their agents are permitted to reproduce and distribute their own articles and notes.

POSTMASTER: Send address changes to Breck Bartholomew, SSAR Publications Secretary, P.O. Box 58517, Salt Lake City, UT 84158. **MISSING OR DAMAGED ISSUE?** Please notify Breck Bartholomew, SSAR Publications Secretary (e-mail: ssar@herplit.com) for a replacement.

SSAR PUBLICATIONS

SSAR publishes seven different series: *Journal of Herpetology, Herpetological Review, Facsimile Reprints in Herpetology, Contributions to Herpetology, Herpetological Circulars, Herpetological Conservation*, and the *Catalogue of American Amphibians and Reptiles* (see below for CAAR details). SSAR members receive prepublication discounts on all *Facsimiles* and *Circulars* and on volumes in the *Contributions* and *Herpetological Conservation* series. A complete pricelist of Society publications is available at: http://www.ssarbooks.com/.

CATALOGUE OF AMERICAN AMPHIBIANS AND REPTILES

The ***Catalogue*** consists of loose-leaf accounts of taxa prepared by specialists, including synonymy, definition, description, distribution map, and comprehensive list of literature for each taxon. Covers amphibians and reptiles of the entire Western Hemisphere. Available for purchase from the SSAR Bookstore (http://www.ssarbooks.com/). Use the prices below to order back issues.

COMPLETE SET: NUMBERS 1–880	check website below for current pricing
INDEX TO ACCOUNTS 1–400: Cross-referenced, 64 pages	$6
INDEX TO ACCOUNTS 401–600: Cross-referenced, 32 pages	$6
SYSTEMATIC TABS (Ten tabs to fit binder: "Class Amphibia," "Order Caudata," etc.)	$6
IMPRINTED POST BINDER (Note: one binder holds about 200 accounts)	$35
INCOMPLETE SET: NUMBERS 1–190	$75
191–410	$85
411–840	$320

To order: make checks payable to "SSAR" and mail to Breck Bartholomew, SSAR Publications Secretary, P.O. Box 58517, Salt Lake City, Utah 84158, USA (fax 801/453-0489). e-mail: ssar@herplit.com. Online orders at: http://www.ssarbooks.com/.

SOCIETY FOR THE STUDY OF AMPHIBIANS AND REPTILES

www.ssarherps.org

The Society for the Study of Amphibians and Reptiles, the largest international herpetological society, is a not-for-profit organization established to advance research, conservation, and education concerning amphibians and reptiles. Founded in 1958, SSAR is widely recognized today as having the most diverse society-sponsored program of services and publications for herpetologists. Membership is open to anyone with an interest in herpetology—professionals and serious amateurs alike—who wish to join with us to advance the goals of the Society.

All members of the SSAR are entitled to vote by mail ballot for Society officers, which allows overseas members to participate in determining the Society's activities; also, many international members attend the annual meetings and serve on editorial boards and committees.

All members and institutions receive the Society's primary technical publication, the *Journal of Herpetology,* and its news-journal, *Herpetological Review*; both are published four times per year. Members also receive pre-publication discounts on other Society publications, which are advertised in *Herpetological Review.*

To join SSAR or to renew your membership, please visit the secure online ZenScientist website via this link:

http://www.ssarherps.org/pages/membership.php

Future Annual Meetings
2011 — Minneapolis, Minnesota, 6–11 July (with ASIH, HL)
2012 — Vancouver, British Columbia, 8–14 August (with World Congress of Herpetology)
2013 — Albuquerque, New Mexico, dates to be determined

ABOUT OUR COVER: *ABRONIA FROSTI*

The arboreal alligator lizards of the genus *Abronia* comprise a group of 28 species, ranging from Tamaulipas and Guerrero, Mexico southward to southern Honduras. The group is characterized by high levels of endemism, with many species confined to cloud forest uplands and in some cases known only from their type localities. Small natural ranges combined with rampant deforestation and profoundly inadequate protection measures offer a bleak prognosis for the future—as grimly recounted by Campbell and Frost (1993. Bulletin of the American Museum of Natural History, No. 216, 121 pp.; available online: http://hdl.handle.net/2246/823).

Given the precarious status of many of these forested ecosystems, a number of species of *Abronia* are seriously imperiled. In a recent assessment of the conservation status of Guatemalan herpetofauna, all 10 species of *Abronia* occurring in that country were considered highly vulnerable (Acevedo et al. 2010. *In* L. D. Wilson, J. H. Townsend and J. J. Johnson [eds.], Conservation of Mesoamerican Amphibians and Reptiles, pp. 406–434. Eagle Mountain Publishing, Eagle Mountain, Utah). Two species—*A. campbelli* and *A. frosti*, both Guatemalan endemics—have been considered extinct based on near-complete destruction of habitat at their only known localities (Acevedo et al. 2010, *op. cit*; Campbell and Mendelson 1998. Mesoamericana 3:21–23).

Recently, however, a small population of *A. campbelli* was rediscovered near the type locality in Guatemala (Ariano-Sánchez and Torres-Almazán 2010. Herpetological Review 41:290–292), offering hope that this species can be saved. The remaining habitat had been reduced to about 400 epiphyte-laden oak trees, an essential habitat element for these lizards. On the heels of that exciting news comes another report in this issue of *HR* of the discovery of a single sub-adult *A. frosti* near the type locality, a species not seen since 1996 despite considerable search effort. Daniel Ariano-Sánchez and colleagues (see pages 196–198) detail this important find, describe what remains of the habitat, and offer critical steps to assure this species' survival.

Our cover image, depicting a sub-adult female *Abronia frosti*, was recorded by **Thomas Schrei**. He used a Canon 40D digital camera and Sigma 180mm f3.5 APO Macro DG lens, mounted on a Manfrotto tripod. The image was shot at f16, ISO 400, with ½ second exposure. Considering that this specimen is the only known living individual of its species, special care was taken to avoid stressing the animal. After many failed attempts in which the lizard persisted in moving, it was allowed to climb the inflorescence of a bromeliad where it finally came to rest. The image was shot in studio against a velvet black background using natural light, with some fill light reflected from white cardboard. Schrei is a student and conservationist living in Guatemala City, in his final year toward a degree in biology at the Universidade del Valle de Guatemala. He works for the local NGO Zootropic as the coordinator of the Natural Reserve for the Conservation of the Guatemalan Beaded Lizard (*Heloderma horridum charlesbogerti*) and associated captive breeding program.

PHOTO BY HUGO VILLAVICENCIO

SSAR BUSINESS

Annual Report (2011) Grants-in-Herpetology Committee

An award in the amount of $500 was made to each of the following individuals:

Conservation.—**Anne G. Stengle**, University of Massachusetts, "Genetic Connectivity Within a Metapopulation of Timber Rattlesnakes (*Crotalus horridus*)."

Education.—**Michelle Lester**, Central Washington University, "Fresh Science: Amphibians".

Field Research.— **Michael Habberfield**, State University of New York at Buffalo, "Investigating the influence of pool and landscape features on the spatial patterns of amphibian breeding in a vernal pool complex in central New York."

Laboratory Research.—**Beck A. Wehrle**, California State University-Northridge, "Why Do Lizards Lounge? The role of sociality in exchanging microbial communities among hatchling *Iguana iguana*."

Travel.—**Denita M. Weeks**, California State University-Northridge, "Fundamental Niche Modeling and Implications of Global Climate Change for the World's Southernmost Gecko."

International.—**Kerry L. Holcomb**, Central Washington University, "Body Temperature and Water Regulation Strategies of Mexican Beaded Lizards (*Heloderma horridum horridum)* in a Tropical Deciduous Forest near Chamela, Jalisco, Mexico"

2010 Grants-in-Herpetology Committee.—Chair: Joshua Kapfer. Reviewers: Rebecca Christoffel, Brian Halstead,

Jerry Husak, Lucas Joppa, Richard King, Charles Knapp, Yu Man Lee, Chad Montgomery, Nicola Nelson, Michael Pauers, Robert Powell, Kevin Zippel.

SSAR congratulates the 2011 GIH recipients and thanks the committee members for their efforts.

Herpetology Courses and Graduate Programs: An Appeal

As an aid for students at all levels, SSAR is now compiling for its website a list of all herpetology courses and graduate programs, worldwide. This will be regularly updated. The list will cover all herpetology courses (or vertebrate biology courses having a sizable content on amphibians and reptiles) that are regularly taught at colleges, universities, biological stations, and other academic institutions anywhere in the world, with name of instructor and detailed course information. The availability of masters and/or doctoral degree-granting programs and names of relevant faculty and their contact information will be included.

Those who wish to have their courses and programs listed should send the following information (in this order, please):

1. Country (State or Province)
2. Institution: name and city
3. Department name
4. Course: number, title, frequency (annual or alternate years), undergraduate- and/or graduate-level course
5. Instructor: name and contact address (email if possible)
6. Graduate herpetology program: note if masters and/or doctoral level
7. Faculty involved in program: name and contact address (email if possible)
8. Special notes: limit to 30 words

Send this information to Prof. Kraig Adler at Cornell University (e-mail: kka4@cornell.edu; postal: Mudd Hall, Ithaca, New York 14853–2702, USA). As soon as the list is compiled, a notice will appear in *Herpetological Review* that will indicate how the list may be accessed and updated. Please help to make this list as complete and useful as possible.

MEETINGS

MEETINGS CALENDAR

Meeting announcement information should be sent directly to the Editor (HerpReview@gmail.com) well in advance of the event.

6–11 July 2011—Joint Meeting of Ichthyologists and Herpetologists (ASIH / HL / SSAR), Minneapolis, Minnesota, USA. Information: http://www.dce.k-state.edu/conf/jointmeeting/

17–22 July 2011—IX Congresso Latinoamericano de Herpetologia, Curitiba, Brazil. Information: http://clah2011esp.blogspot.com/

20–23 July 2011—Biology of the Rattlesnakes Symposium, Tucson, Arizona, USA. Information: http://www.williamkhayes.com/rattlesnakes/

27–30 July 2011—34th International Herpetological Symposium, Fort Worth, Texas, USA. Information: http://www.kingsnake.com/ihs/

10–11 August 2011—Annual Meeting of Southwest Partner in Amphibian and Reptile Conservation (SW PARC), Tucson, Arizona, USA. Information: www.swparc.org/meetings.html

15–16 August 2011—Current Research in Sonoran Desert Herpetology V, Tucson, Arizona, USA. Information: www.swparc.org/meetings.html

14–17 August 2011—9th Annual Symposium on the Conservation and Biology of Tortoises and Freshwater Turtles, Orlando, Florida, USA. Information: www.turtlesurvival.org.

17–18 August 2011—12th Annual Meeting of Northeast Partners in Amphibian and Reptile Conservation (NEPARC), Millersville, Maryland, USA. Information: http://www.pwrc.usgs.gov/neparc/

25–29 September 2011—Joint 16th SEH European Congress of Herpetology & 47th DGHT Deutscher Herpetologentag (annual meeting of the German Society for Herpetology and Herpetoculture, scientific part), Luxembourg. Information: http://www.symposium.lu/herpetology

30 September–2 October 2011—47th DGHT-Nachzuchttagung (annual meeting of the German Society for Herpetology and Herpetoculture, herpetocultural part), Trier, Germany.

8–14 August 2012—World Congress of Herpetology 7, Vancouver, British Columbia, Canada (together with SSAR, HL, ASIH). Information: http://www.worldcongressofherpetology.org/

2–7 September 2012—4th International Zoological Congress (IZC), Mount Carmel Campus, University of Haifa, Haifa, Israel. To receive the first and subsequent meeting announcements, contact the organizers at: izc2012@sci.haifa.ac.il.

NEWSNOTES

Roncadell Digital Library

Roncadell—a conservation organization based in Valencia, Spain—has established a digital library containing a number of important herpetological works long out of print, as well as a few modern titles. To view the catalogue and to download digital files, please visit their website at:

http://roncadell.jimdo.com/biblioteca-digital/llibres-antics/herpetologia-i-peixos/

Herpetological Reunion at Louisiana State University, Baton Rouge

Several former graduate students and friends of Dr. Douglas A. Rossman gathered with Doug and his spouse Sharon for a second reunion at the LSU campus from 2–6 April 2011. Present at the celebration were Doug's former students Janalee P. Caldwell, Donald E. Hahn, Jeff Boundy, Kenneth L. Williams, and Larry David Wilson. Guests included Laurie J. Vitt and Viola Williams. Robert A. Thomas from Loyola University joined "Rossman's Renegades" to recount tales from USL (now University of Louisiana at Lafayette). Former students unable to join the reunion, but remembered, were Frank T. Burbrink, Darrel R. Frost, Richard M. Blaney, Patricia K. Blaney, and Edmund D. Keiser. Also remembered were three colleagues now deceased: Ernest A. Liner, Gerald C. Schaefer, and Alexander Varkey.

Apart from enjoying the local world-class Cajun cuisine, the attendees reminisced with one another, admittedly with some embellishments. In addition, Christopher Austin provided a tour through the LSU Museum of Science herpetological range; thanks are due him for making arrangements for our visit. The highlight of the gathering was Doug's recounting of his move to Iowa and his activities in both herpetology and Norwegian mythology since his retirement. Long a passion of Doug's, his work in Norwegian mythology has resulted in the publication of five books since his retirement.

PHOTO BY PHOTO BY L. J. VITT

Doug Rossman and former grad students at recent LSU herp reunion. L–R: Ken Williams, Jan Caldwell, Doug, Don Hahn, Larry Wilson, and Jeff Boundy.

Jan and Laurie made a presentation on their work in Brazil and Don showed slides (yes, slides) of his early trips to Honduras, including to the Bay Islands with Larry and his then new wife Elizabeth. Later, at one of the dinners, Don was a hit with an impromptu comedy and magic show.

This reunion was the second get-together. The first took place in 1998 at LSU in connection with Doug's retirement from the institution. That gathering was a bit more formal and was emceed by Larry. Each of Doug's students rose to tell his or her story since graduation, again salted with appropriate embellishments. We all are looking forward to the next reunion in 2024.

Journal of Natural History Education and Experience

The *Journal of Natural History Education and Experience*, a publication of the Natural History Network, is an electronic, peer-reviewed, open-access journal. Its purpose is to foster a renaissance in natural history education and appreciation by providing a forum for disseminating information on views on the place of natural history in society and techniques, curricula, and pedagogy for natural history education at all levels: K–12, undergraduate, graduate, and general public.
Recent articles include:

- Rewilding Natural History (Peter Kahn and Patricia Hasbach)
- Revitalizing Natural History Education by Design (M. Kolan and W. Poleman)
- Natural History from the Ground Up: developing a college-level natural history program in the new millennium (D. Gilligan)
- A Bird in the Hand: A placed-based, hands-on curriculum in ornithology (S. Trombulak)
- Teaching Natural History and the Spirit of Place (F. Taylor and J. Tallmadge)

The Natural History Network (naturalhistorynetwork.org) is an affiliation of teachers, scientists, and nature writers who seek to promote the values of natural history through discussion and dissemination of ideas and techniques on its successful practice to educators, scientists, naturalists, artists, writers, the media, and the public at large.

The journal seeks papers that provide perspectives on natural history as a mode of engagement with the world as well as information that will promote the development of natural history curricula and are generally accessible to natural history educators. Content of the journal ranges from the applied to the philosophical, but entirely focused on the principles or practice of natural history education and experience.

Educators and practitioners who have perspectives or successful curricula that they would like to share are especially encouraged to submit articles for publication.

For more information, visit www.jnhe.org or write to Steve Trombulak, editor of the *Journal of Natural History Education and Experience*, at trombulak@middlebury.edu.

CURRENT RESEARCH

The purpose of Current Research is to present brief summaries and citations for selected papers from journals other than those published by the American Society of Ichthyologists and Herpetologists, The Herpetologists' League, and the Society for the Study of Amphibians and Reptiles. Limited space prohibits comprehensive coverage of the literature, but an effort will be made to cover a variety of taxa and topics. To ensure that the coverage is as broad and current as possible, authors are invited to send reprints to the Current Research section editors, Joshua Hale or Ben Lowe; e-mail addresses may be found on the inside front cover.

A listing of current contents of various herpetological journals and other publications is available online. Go to: http://www.herplit.com and click on "Current Herpetological Contents."

Intercontinental Dispersal in a Fossorial Reptile

Intercontinental dispersal has been a feature of the biogeographic history of many animals, either by passage across land bridges, or by long-distance oceanic rafting. The family Dibamidae consists of burrowing, essentially limbless lizards and has traditionally been split into two geographically disjunct clades: *Anelytropsis*, a monotypic genus with a restricted distribution in northeastern Mexico, and *Dibamus*, containing approximately 20 species occurring in southeast Asia. In this study, the authors collected molecular data (one mitochondrial and six nuclear genes) for nine dibamid species including *Anelytropsis* and used Bayesian methods to reconstruct a phylogeny and to estimate divergence times among the dibamid lizards. These analyses recover three deeply divergent but morphologically conserved clades: mainland and insular *Dibamus* clades and an *Anelytropsis* clade. Furthermore, all analyses find *Anelytropsis* to be the sister of one of the two *Dibamus* clades (to which clade analyses fail to distinguish with confidence). The dating analysis places the origin of these three lineages to between 90 and 49 million years ago. Therefore, if the intercontinental dispersal which must have occurred to lead to this disjunct distribution occurred by way of a land bridge, it most likely occurred across Beringia in the late Palaeocene or Eocene. Alternatively, oceanic-rafting across the Pacific remains a possible explanation. Additionally, the discovery of the deep genetic divide separating *Dibamus* is surprising, and given the tremendous similarity between species in both clades, constitutes a remarkable example of morphological conservatism.

Townsend, T. M., D. H. Leavitt and T. W. Reeder. 2011. Intercontinental dispersal by a microendemic burrowing reptile (Dibamidae). Proceedings of the Royal Society of London, Series B (*in press*). doi: 10.1098/rspb.2010.2598.

Impact of Overwintering Conditions on *Bd* Infection and Mortality in Toads

As host/pathogen dynamics can be severely impacted by temperature variations, factors such as global warming are predicted to influence future patterns of disease. Despite this potential, few studies have experimentally tested the effects of changing temperature on host/pathogen interactions. In this study, the authors have experimentally tested the effect of overwintering temperature on susceptibility of common toads, *Bufo bufo*, to infection and mortality caused by the amphibian pathogen *Batrachochytrium dendrobatidis* (*Bd*). Two groups of newly metamorphosed toadlets were subjected to one of two overwintering treatments. The first saw toads held at 8°C for 36 days, 4°C for 11 days followed by 8°C for a further 36 days. The other group was held at 8°C for 16 days, 4°C for 51 days followed by 8°C for a further 16 days. Following overwintering (and a 16 day recovery period), animals from both treatments were either infected by a high dose of *Bd*, a low dose or a control treatment. Infection status was then determined. Toads from the warmer overwintering regime suffered a greater chance of infection, however once established, the proliferation of *Bd* was higher in toads from the colder overwintering treatment. There was no difference between treatments in survival, or in any consistent influence of disease on survival for that matter. Instead, condition, mass and mass lost over winter was the best predictor of toadlet survival, which led the authors to conclude that larval growth is a more important to survival of toadlets than overwintering conditions or *Bd* infection rate.

Evolution of a Cryptic Species Complex in Northern Australia

Cryptic speciation is the process whereby lineages separate and accumulate genetic differences without concurrent morphological divergence. This phenomenon provides an interesting opportunity to investigate morphological stasis and determine if phenotypic stability is a consequence of either adaptive or non-adaptive processes. In this study, the authors have examined a pair of sister species occurring in northern Australia: the agamid lizards *Diporiphora magna* and *D. bilineata*. A phylogenetic analysis based on one mitochondrial gene (ND2) and a nuclear gene (RAG1) revealed eight deeply divergent and geographically discrete clades. No consistent morphological differences were observed between the clades, confirming this system's status as a cryptic species complex. Morphological and ecological data was collected, analyzed in principal component analyses, and compared with phylogenetic data to determine whether evolution in these characters fit models of neutral drift (Brownian motion) or constrained or correlated evolution. These phylogenetic comparative methods favored a model of constrained evolution, suggesting adaptive processes are important in maintaining morphological similarity among clades. The authors suggest that the homogenous habitat structure, but highly variable environmental conditions has promoted morphological stability in these species. This study highlights the potential for adaptive processes to maintain morphological stasis and that dynamic environments may select for cryptic species.

Smith, K. L., L. J. Harmon, L. P. Shoo and J. Melville. 2011. Evidence of constrained phenotypic evolution in a cryptic species complex of agamid lizards. Evolution (*in press*). doi:10.1111/j.1558-5646.2010.01211.x.

Behavioral Alleviation of the Costs of Reproduction in *Anolis* Lizards

The costs of reproduction for a female can be alleviated by modification of behaviors during reproductive periods. In this study, the authors examined these behavioral modifications in green anole lizards, *Anolis carolinensis*. The effect of reproductive load on three behaviors (locomotion, social displays and foraging) was examined. Observations were made of female lizards in the field and then focal individuals were captured and their reproductive load was determined (by measuring the total amount of reproductive tissue: eggs, follicles and oviducts). Locomotion and social display behavior both declined with reproductive load, however no effect of reproductive load on foraging behavior was detected. In the second part of the study, the authors conducted analyses to determine if these behaviors and reproductive loads were phylogenetically correlated across eight additional *Anolis* species. No associations were found between the evolution of reproductive load and any of the behaviors, and may represent varying life history strategies or selective ecological pressures across *Anolis* species instead.

Johnson, M. A., J. L. Caton, R. E. Cohen, J. R. Vandecar, and J. Wade. 2010. The burden of motherhood: the effect of reproductive load on female lizard locomotor, foraging and social behavior. Ethology 116: 1217–1225.

Ageing and Fitness Correlates Determined in a Wild Population of Lizards

Ageing can have complex and interrelated impacts on a range of fitness traits, and therefore, it is essential that it is accounted for in studies investigating potentially age-related variation. Despite this, due to the complex nature of identifying age components of variation, especially in wild populations, they are rare. In this study, the authors have taken a comparative approach to investigation ageing in a wild population on the common lizard, *Lacerta* (*Zootoca*) *vivipara*, in southern France. Five fitness components were examined and three physiological traits (resting metabolic rate, corticosterone level, cell-mediated immunity). Age-related variation was discovered in multiple fitness aspects, including senescence in female reproduction, measured by litter success. Further, old females had a higher metabolic rate and T cell-mediated immune response compared to young females. Interestingly, only females that had a high investment in reproduction when young, displayed senescence later in life. This trade-off is expected theoretically but is rarely observed in the wild. Some of the effects of ageing were also related to differences in environment and individual characteristics. This study highlights the importance of taking an integrative approach to studies of ageing, as it is a complex and interrelated process, potentially involving a range of fitness traits.

Impact of Environmental Conditions on Predator Responses in Tadpoles

Behavioral plasticity is a valuable capability, especially in unpredictable environments. However, an organism's ability to behaviorally respond to one environmental factor may be constrained by another, seemingly unrelated environmental factor. For frogs, a well-studied phenotypically plastic response relates to hatch timing. Embryos have been demonstrated to hatch in response to predators, certain abiotic conditions and changes in resource availability. In this study, the authors have examined the impact of environmental conditions on hatch timing in the neotropical treefrog, *Dendropsophus ebraccatus*. This frog lays eggs both above the water (attached to leaves) and directly in the water, exposing these eggs to different desiccation risks. The impact of desiccation on predator-induced hatching and escape success from two predators (terrestrial *Azteca* ants and aquatic tadpoles) was investigated. In response to both predators, eggs hatched prematurely (up to 67% earlier than unpredated clutches). however, when exposed to desiccating conditions, egg clutches subjected to attacks from the *Azteca* ants suffered lower predator escape success than those from hydrated clutches of either predator treatment. Indeed, desiccated eggs recently placed in the water showed no difference in early hatching success relative to eggs eggs having been submerged in water long term. The reduction in predator escape from desiccated clutches probably impacts recruitment in wild populations, and highlights the importance of other environmental factors in mediating phenotypically plastic responses.

Touchon, J. C., J. Urbina and K. M. Warkentin. 2011. Habitat-specific constraints on induced hatching in a treefrog with reproductive mode plasticity. Behavioral Ecology (*in press*) doi: 10.1093/beheco/arq192.

Impact of Agricultural Land Use on Stream Dwelling Turtles

Anthropogenic modifications to riparian habitat can have serious consequences for stream dwelling organisms. In this study, the authors examined whether the diversity and abundance of freshwater turtles differed between agricultural riparian zones, and those that had been undisturbed or restored. This study was conducted in the Lower Flint River Basin (LFRB) in south-west Georgia, USA, which possess a high diversity of freshwater turtles. In total, nine species were encountered, from two streams within the LFRB. Diversity (species evenness) was positively correlated with the amount of undisturbed landcover in the riparian habitat. However, associations between riparian habitat and abundance differed between species. For some species, abundance increased in less-forested, more disturbed sections of stream, but for the state-protected and endemic *Graptemys barbouri* (Emydidae), abundance was lowest in disturbed riparian zones. The impacts of agriculture on species diversity could relate to the availability of prey species in these stream sections which are sensitive to runoff. This study indicates physical alterations such as increased sedimentation or a reduction in nesting sites may reduce the number of species that can be supported in a stretch of stream.

Sterrett, S. C., L. L. Smith, S. W. Golladay, S. H. Schweitzer and J. C. Maerz. 2011. The conservation implications of riparian land use on river turtles. Animal Conservation 13:38–46.

Artificial Water Points Assist Cane Toads in Invading Arid Zones

In many cases, biological invasions occur from "invasion hubs," satellite populations that once established, facilitate expansion. By concentrating management effort on these invasion hubs, the spread of invasive species may be contained. While there is good theoretical support for this management strategy, it has rarely been practically demonstrated. Artificial water points (AWP) have been installed by humans throughout arid landscapes, increasing the availability of standing water. The increase in AWP has potentially opened up many otherwise inhospitable landscapes to colonization by invasive species. In this study, the authors have examined the importance of AWP in the invasion of northern Australia by the Cane Toad, *Bufo marinus*. They experimentally excluded toads from some AWP with fencing and by hand-counting the toads trapped within the fences and comparing toad abundance in areas with and without access to AWP, they demonstrated that AWP do provide dry season refuges for the toads as well as provide a resource subsidy. The authors suggest that AWP operate as invasion hubs for cane toads in arid Australia. The authors also modelled the impact of excluding toads from AWP throughout arid Australia, and predicted that this would reduce the area across which toads could colonize by 38%. This study highlights the importance of anthropogenic landscape modification in the spread of invasive species and illustrates the potential for controlling the spread of these species through cordoning off invasion hubs.

Logging Activity Does Not Impact Behavior of Timber Rattlesnakes

Forest management activities have the potential to profoundly alter the landscape, and as a consequence, may have serious impacts on the animals that live in these landscapes. For this study, the authors have examined the impact of commercial logging on the behavior of Timber Rattlesnakes (Viperidae: *Crotalus horridus*) in Pennsylvania, USA. Over a four-year period, behavior was examined using radiotelemetry, mark-recapture and visual surveys in areas both prior to and following logging. Direct observations of mortality during logging was low (observed mortalities represented less than 2% of the population per year), as were rates estimated from the mark-recapture data (less than 7%). Following logging, snakes maintained their previous ranges, and actually increased the divesity of utilized habitats to include sites in logged areas. Indeed, contrary to the concern that gravid females might suffer disproportionate mortality, the authors posit that their preference for areas with favorable thermoregulatory opportunities kept them out of the logging areas until operations were completed.. The authors propose that the most significant cause of mortality was direct killing by loggers, and suggest that to reduce the impacts of logging on rattlesnakes, workers in this region should be prohibited from killing encountered snakes.

African Geckos, Coalescent-based Species Delimitation Methods, and the ICZN

As methods for acquiring diverse DNA sequence data continue to accumulate, methods for analyzing these data are also improving. For a while now, researchers have had the ability to evaluate hypotheses of speciation using data from across the genome, rather than relying on single molecular markers or detectable morphological differentiation. More recently, advanced methods for extracting the underlying "species tree" from a suite of potentially discordant "gene trees" have opened the door for more rigorous tests of speciation. The authors of a recent study[1] investigated species limits in a clade of West African geckos (Gekkonidae: *Hemidactylus fasciatus* complex) using one of these new methods: Bayesian species delimitation (BSD). This method exploits the genealogical information inherent in DNA sequence data to evaluate hypotheses of species limits under expectations derived from coalescent theory. Using sequence data from five nuclear DNA genes from samples collected across the distribution of *H. fasciatus*, the authors conducted a genotype clustering analysis to identify genetic populations and constructed a species tree for these populations using the sequence data. Subsequently, they conducted an analysis which utilized coalescent theory to simulate gene trees based on the sequence data; these simulated trees were used to differentiate between ancestral polymorphisms and post-divergence gene flow (the latter being viewed as evidence against speciation). The structuring analysis identified four genetic groupings and the BSD analysis found strong support for all four groups being genetically independent and therefore distinct species. The same analysis conducted with the hypothesis of each population being a separate species found the same results with the exception of an insular locality representing a fifth species. The authors describe these four lineages as species, citing clustering with the respective holotype in their BSD model as the species diagnoses.

Several researchers subsequently published a commentary[2], taking exception to the use of model-based clustering analyses to describe new species and indicating that these analyses should be accompanied by explicit, character-based diagnoses (which could include molecular characters). While conceding that the focus on characters may be artificial, they argue that species descriptions lacking diagnostic characters are in strict violation of the International Code of Zoological Nomenclature (ICZN) and could lead to taxonomic inflation (a precipitous rise in "superficial" species descriptions that could ultimately undermine conservation efforts). Finally, they contend species delimitation should incorporate data from multiple, independent categories and species descriptions based solely on clustering in an analysis performed under a particular model should be avoided.

The authors of the original article responded in an invited reply[3] by addressing the claim of taxonomic inflation and the validity of solely using BSD to identify species. They argue that BSD simultaneously incorporates multiple, independent lines of evidence and is therefore less prone to taxonomic inflation than methods relying on a single character, such as a single-locus gene tree (as under the Phylogenetic Species Concept). Furthermore, they maintain that coalescence of independent genes across the genome is a more intrinsic feature of speciation than either the acquisition of unique morphological characters or single-gene reciprocal monophyly, making BSD a superior tool in the effort to rigorously identify species. Finally, they indicate that more detailed and ICZN-compliant descriptions of the species identified in their study are forthcoming.

The Snake Handles

The Reptile House at The National Zoological Park in Washington DC is a splendid example of "Associationist" zoo design: exotic style used to enhance the spectacle of zoo going. The ten panels on the original entrance doors alternately display a lumbering *Stegosaurus* and battling yin-yang *Protoceratops* (Fig. 1, left). The panels are of gesso (a preparation of plaster of Paris, glue, and sometimes horsehair). Each of the four doors to the Reptile House held a bronze door pull which consisted of a ring formed by two intertwined serpents. It is generally assumed that John Joseph Earley was the artist connected with the design and execution of these handles, although where they would have been cast is not known.

In spirit, if not actual design, they are reminiscent of the staff of Mercury. These serpents are entwined, rather than opposing as on the caduceus. In Chinese mythology, the world was surrounded by two entwined snakes, symbolizing the power and wisdom of the creator.

In its original configuration, the art went beyond merely visual and into the tactile—one had to pull on the snake handle to open the doors. Therefore, most visitors would have had to place their hand on a reptile before entering the building. In 1980 the Reptile House was renovated and the entrance doors were refurbished and placed inside the building to the entrance of what was called HerpLab (now known as Resource Room). The original handles were replaced in 2005 with replicas cast through the lost wax process at a local foundry (Fig. 1, right).

A photograph of the original entrance door and herpetological history of the Zoo may be seen in Murphy and Xanten (2007). (Herpetol. Rev. 38:262–373).

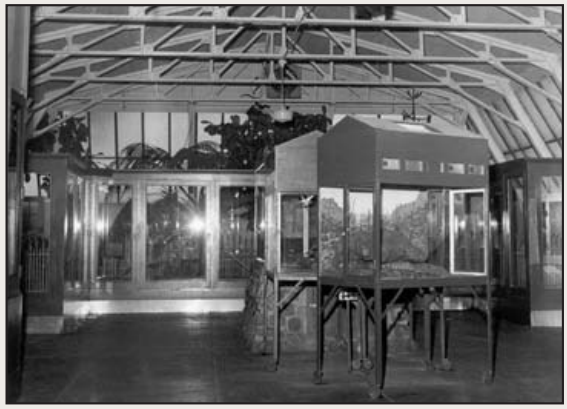
Snake Crushes Bus

The Copenhagen Zoo in Denmark has designed one of the most intriguing advertising campaigns: a Boa Constrictor constricting a city bus. Notice how cleverly they altered the apparent roof of the bus. The advertising agency was Bates Y & R in Copenhagen, Creative Director was Ib Borup, and Art Director was Peder Schack. Thanks to Britta Benzer Ankersen, Michael Jorgensen, and Gerard Visser for providing this image.

Jolly Green Giant

Curator of Herpetology Steve Reichling and Graphic Designer Tonya Kuhl, both of the Memphis Zoo in Tennessee, sent this poster of a vegetative Komodo Dragon for an event held at the Zoo in 1998. The format was developed by the company Good Advertising.



Reptile Buildings During the Great Depression in the 1930s

"But should snakes get any money at all? They are not the fuzzy, feel-good animals that one might have imagined would have received taxpayer money at a time when many Americans were going hungry." This was a question asked by Mrs. Charles J. Dolan in her editorial to a St. Louis newspaper: "What are the St. Louisans thinking of to let the gentlemen of the Zoo Board go ahead without protest with their amazing proposal to squander $100,000 of the taxpayers' money on a climax of absurdities —and worse—a chamber of horrors that nobody wants—a snake house."

—Jesse C. Donahue and Erik K. Trump, 2010

Credit: undated photograph by Franklin Williamson, courtesy of Zoological Society of Philadelphia, provided by Brint Spencer.

Postcard of original Reptile House, now bird house, at Cincinnati Zoological and Botanical Gardens. Credit: provided by Brint Spencer.

In their book *American Zoos During the Depression. A New Deal for Animals* (2010, McFarland & Co., Jefferson, North Carolina; ISBN: 978-0-7864-4963-7), authors Donahue and Trump follow the amazing growth of zoo construction in the United States supported by federal programs. In Chapter 4, "Why snakes? The spectacle and science of snakes," they document the design and development of many reptile buildings that occurred during the 1930s. Some of the most spectacular zoo buildings were built or improved at that time: National (Washington, DC), Toledo, St. Louis, Brookfield, Cincinnati, San Antonio, San Diego, Buffalo, and Philadelphia. As a testament to their durability and beauty, some still are operational today.

It may surprise the reader, but the production of antivenin in North America during this period was supported in large part by zoo herpetologists, who provided venom to the manufacturers, raised public awareness about snakebite treatment, and distributed antivenin.

JAMES B. MURPHY, *Section Editor*

RESPONSES TO JOE MENDELSON'S ESSAY

In the last issue of *HR*, Joe Mendelson from Zoo Atlanta authored a thought-provoking essay on what it means to be an amphibian biologist today. His piece elicited many responses and has generated much discussion. In this issue, we are pleased to offer four companion essays from Kraig Adler, Harry Greene, Michael Lannoo, and Larry David Wilson. The focal species of Mendelson's essay, *Ecnomiohyla rabborum* (Rabb's Fringe-limbed Treefrog, now reduced to two living individuals, both male), is shown here with George B. Rabb. The frog was named in honor of herpetologists and conservationists George and Mary Rabb.

No White Flags!

Joe Mendelson's essay provides heart-breaking affirmation of the state of the planet: even with the best efforts humanity can muster, we will lose a lot of existing biological diversity before this crisis bottoms out. Other commentators have stated that Polar Bears and Tigers are already toast, too far gone to save in the wild—can you imagine conceiving of that possibility when we were kids, that the largest mammalian carnivores on Earth would come so close to extinction in our lifetimes? Equally disturbing are a variety of looming threats—as just unstudied one example, what if

Harry Greene examining a Bolson Tortoise (*Gopherus flavomarginatus*), among a group of about two dozen that have been restored to their late Pleistocene range in New Mexico.

some critical factor changed just enough that dinoflagellates and diatoms, which provide much of our oxygen, crashed as suddenly and mysteriously as the Golden Toad? And in the face of this overall situation, conservationists and environmentalists are too frequently acting as if business as usual is sufficient, or at least all that we can hope to accomplish.

Can we find reasons for hope? Well, the undergraduates I teach are bright, talented, hard working, and idealistic—maybe they can pull off what we've thus far failed to accomplish, and I surely hope so. What else? Thanks to the Pleistocene rewilding initiative and Ted Turner's Endangered Species Foundation, Bolson Tortoises have a toehold back in New Mexico (Donlan et al. 2006; Truett and Phillips 2009) and thus TWO latitudinally disparate populations with which to face climate change. We have folks like Joe Mendelson attempting other bold, risky endeavors in the face of withering criticism from some of his peers. And there's the cowboy I met a few years back in a bar near the Pecos River, who when asked if he'd shot a big Indigo Snake, replied, "Hell no, why would we do that? Our boss won't even let us kill those ol Diamondbacks anymore, except right around the foreman's house, cause he's got kids and all."

Perhaps there's still room for optimism, and our rallying cry should be "no white flags!"

Amphibian Extinction Crisis: The Key Threat of Habitat Loss and a Potential Major Role for Amateurs

I love amphibians. I once said that to one of my molecular biology colleagues at Cornell, who looked at me like I was totally crazy. The readers of *Herpetological Review* will know what I meant. Like many of them, I became fascinated with frogs and salamanders when I was a boy. Much later, amphibians became my primary study animals for behavioral research as well as some systematics and faunal work. Long ago I came to have a deep respect for the ways in which they make their livings and for their dazzling diversity and aesthetic beauty. Thus, Joe Mendelson's article in the March issue came as a real jolt—although not an altogether unexpected one, unfortunately. The world that he, Mike Lannoo, Karen Lips, Kevin Zippel, and my other young colleagues live in is far different from the one that those of my generation have enjoyed. While the chytrid fungus is the current plague, an even more insidious one is the loss of habitat—one pond here, a forest patch there, or a stretch of stream or riverbank. And this scourge is happening in the USA and in Europe as much as it is in the tropics. Joe's depressing observations have caused me to reflect on my own experiences with amphibians, the impacts that we have had on them, and their future prospects for survival.

PHOTO BY DOLORES ADLER

Kraig Adler on a field trip in Ithaca, New York, with plastic box of salamanders, April 2011.

As high school students in Ohio in the 1950s, David Dennis, who became a natural history artist and photographer, was my constant field companion. We first explored Ohio for herps, then West Virginia, and finally worked our way south to Kentucky, Virginia, and North Carolina by the time we were in college in the early 1960s. Thus, we came to know many of the localities immortalized by E. R. Dunn, the first plethodontid expert: Grandfather Mountain, White Top, and Clingman's Dome; the French Broad River; and Yonahlossee Road (not the current road by that name). Dave and I have also enjoyed the Nantahala Mountains, Tusquitee Bald, Burke's Garden, and Bat Cave, among many other places. It was just east of Boone, North Carolina, late one night about 1960, that we saw our first Yonahlossee Salamander (*Plethodon yonahlossee*) (Fig. 1). I can still vividly remember Dave, Steve Tilley, another regular field companion, and me yipping and yelling at seeing that most handsome of salamanders. (Of course, we didn't yet have it in our hands, and that can be a real challenge.) In those days, we could stop at outcrops along the road or in ravines below bridges and find salamanders in large numbers almost anywhere we looked, especially if it was after nightfall.

PHOTO BY DAVID DENNIS

FIG. 1. *Plethodon yonahlossee* (Yonahlossee Salamander) during courtship in the field.

In August 1976, Dave and I led a three-car caravan after the SSAR meeting in Oxford, Ohio, for three days of salamandering in the Southern Appalachians. We saw and photographed 26 species (and those were the days before Dick Highton and Steve Tilley described a plethora of new plethodons and desmogs from that region). Tim Halliday, the British herpetologist and future amphibian conservationist who was visiting the USA for the first time, was part of our group. (He has only three species of salamanders in his country, all of them newts.) Late one night at Old Yonahlosee Road, along the foot of Grandfather Mountain near Linville, North Carolina, we observed literally hundreds of salamanders. Conditions were perfect: it was breeding season, warm, and a very light rain was falling. We saw eight species of *Desmognathus*, *Eurycea*, *Gyrinophilus*, and *Plethodon* in our headlamp beams. All were crawling about and many of them even high into the vegetation to feed. Several were courting including the Yonahlossees. Tim got a bit giddy. It was truly a Homeric scene!

Over the years, I have taken small groups of Cornell students to the Southern Appalachians for salamanders. To see a Cave (*Eurycea lucifuga*), a Red (*Pseudotriton ruber*), or a Green (*Aneides aeneus*) salamander for the first time is unforgettable. They make an impression on a student. By the 1980s, however, my favorite haunts were being converted to gated retirement communities, parking lots, and golf courses, even near Linville and the Yonahlossee Road itself. For me, one of the most telling experiences was at a meadow stream a few km south of Boone along Route 105 towards Linville, just behind the Lebanon Baptist Church. That was always the best place to reliably find the Long-Tailed Salamander (*Eurycea longicauda*; Fig. 2). They were very active in the tall grass along the edge of Willow Brook, making them tough to collect without damaging that magnificent tail. These animals were abundant there for decades until the early 1990s when, after only a two-year hiatus between our visits, we returned to find the area had been completely developed for upscale housing. I thought we must have taken a wrong turn, so went back to a landmark (the church) and tried again, only to find that the stream as I knew it was gone, and so too were those beautiful salamanders.

Dave Dennis and I once witnessed a local extinction. In 1961, we visited the type locality of the tiny Seepage Salamander (*Desmognathus aeneus*) together with Jesse C. Nicholls, Jr. In 1946, he had collected the types for Sherman C. Bishop, a specialist on salamanders who later wrote the standard handbook on the topic. When we arrived at the wooded, sphagnum-covered site, along a small tributary of Peachtree Creek about 5 km east of Murphy, North Carolina, bulldozers were clearing the area. When the operators took their lunch break, the three of us rushed in to search for salamanders. We eventually collected about 50 of them (Fig. 3). (These topotypes are now at the Carnegie Museum in Pittsburgh.) After lunch ended, the bulldozers started up again and cleared the rest of the site of all of its trees. The type locality is now in cultivation and unsuitable habitat for salamanders. It was depressing to watch the total destruction of an ideal habitat for this patchily distributed and uncommon species.

Overzealous scientific collecting is sometimes to blame for severe habitat destruction. In 1964, I visited the Sierra Madre del Sur of southern Mexico and along a stream at 1070 m on the southwestern slopes of Cerro Teotepec in Guerrero I found an odd hylid frog that I could not identify (Fig. 4). A few weeks later, our party of three encountered a much larger one composed of an American professor and his students. In my enthusiasm, I showed the professor my frogs, which he did not recognize either, and I stupidly noted where they were found. As luck would have it, our party revisited the Teotepec site a couple of weeks later and found it ravaged. Most of the emergent vegetation was uprooted and nearly all of the arboreal bromeliads had been dropped to the ground and dismembered. I half suspected what had happened and this was confirmed when, a month later in Oaxaca, we encountered the professor and his party again. Groups of students had been assigned to each side of the stream to tear up the water plants. Other students were sent up into the trees to throw down the bromeliads for their colleagues to tear apart on the ground. In fact, despite all the devastation, they got no adults

FIG. 2. (**left**) *Eurycea longicauda* (Long-tailed Salamander). FIG. 3. (**center**) *Desmognathus aeneus* (Seepage Salamander). FIG. 4. (**right**) *Hyla* (now *Exerodonta*) *pinorum* (Mexican Pine Woods Treefrog), Guerrero, Mexico. This species may now be extinct.

at all! (I had taken five males on my first visit by patiently locating them by their calls at night, without disturbing any vegetation.) I learned my lesson and, when I described three new hylids from this trip I purposely did not reveal precise directions to the type localities, although these data are in my field notebook. I don't know precisely what effect the damage at the Teotepec site had on the amphibians, but certainly that stream site was less habitable for frogs for a long time to come. Unwittingly, I had contributed to this desecration and I have never forgotten my role in it.

My attitude towards amphibian conservation and the protection of habitats in which they live has changed as a result of these and other experiences I've had. I am happy to see the emergence of hobbyist groups, like Tree Walkers International (TWI), that promote healthy wild populations of amphibians. Among other beneficial projects, TWI provides information for volunteers to create amphibian habitats in their own backyards. And my attitude toward more radical approaches may be surprising. For example, I harbor a waning hope that the Golden Toad (*Incilius periglenes*) of Costa Rica may still survive, not in the wild perhaps, but as a breeding colony kept by some amateur terrarist who has not divulged its existence. Because this species is rigidly protected under IUCN listing, any owner of live specimens in the USA could be prosecuted under the Lacey Act. The owner would be loath to reveal that he or she possesses these toads, but the real losers are the toad, Costa Rica, and all of us. If such a captive colony exists, we need to find a way to absolve the owner in order to recover this exquisite animal, one of the most sexually dimorphic frogs in the world. If the owner would have to pay a fine, I would happily contribute to the fund.

Let me go one step further. I believe we need to reevaluate the role of serious amateurs who, with patience and skill, have learned how to breed so many species of amphibians. Some are actually the world experts on particular species. We should ask them to help us conserve endangered species. Amphibian Ark (AArk), an NGO sponsored by the world's zoos and aquariums, is heavily involved in captive-breeding efforts, but AArk does not have the capacity to preserve all of the endangered species. At best, the resources of such organizations might be sufficient to save 10% of the endangered species. Who will help with the rest? If we continue to take a purist approach and say that such breeding can only be handled by accredited zoos, universities, and other public institutions, then surely many—probably most—species of disappearing amphibians are doomed. But if zoos were to provide breeding stock to amateurs (who would have to be properly certified), then amateurs must be willing to reciprocate in helping to restock zoos and provide stock for reintroductions in the wild. The permitting authorities would have to be receptive, but currently the United States Fish & Wildlife Service is not. In Australia, on the other hand, the first place the government turns is to the hobbyist community, Kevin Zippel informs me. I realize that the issues involved are not simple and all parties need to rise above their parochial interests. We must find a way to certify qualified amateur terrarists and ask for their help in this noble effort.

A novel effort involving amateurs has been underway since 2009 to breed the endangered Oregon Spotted Frog (*Rana pretiosa*) (see http://seattletimes.nwsource.com/html/localnews/2009421766_inmatefrogs06m.html). With guidance from Marc Hayes, a researcher with the state's wildlife department who is well known to herpetologists, two inmates at the minimum-security Cedar Creek Corrections Center in Washington State have been hatching frogs from eggs each April. They hold the tadpoles and froglets in plastic pools where they are fed every two hours and the water is refreshed regularly. Perhaps because of the inmates' intensive care for their animals, the mortality they observe is lower than that reported at several zoos where this species is also being bred. More than 1000 young frogs are then released each fall at sites where this species was once abundant. Why couldn't this low-cost method for headstarting endangered amphibians be copied elsewhere? I am told that a similar plan is being considered in New York State to headstart Hellbenders (*Cryptobranchus alleganiensis*). This idea could also be expanded to exotic species. Because of high security in a

prison facility, some of the Fish & Wildlife Service's concerns would be alleviated.

I do not wish to become an "extinction biologist," Tim Halliday's morbid term, or what Joe Mendelson calls a "forensic taxonomist." If we are to avoid this fate, we must think in new ways and find new solutions to old problems. And we must do it very quickly. Will a partnership with the amateur community make a difference in the long run? I don't know. Is it worth the gamble? Certainly. Are there better ideas? Let's hear them.

No Retreat, Baby, No Surrender

Having written or edited more words on amphibian declines and malformations than most, it would be easy for me to look big picture and give up. We see the über rich convert, directly or indirectly, our favorite ecosystems into gated communities of manicured McMansions, copping an attitude of "this land was made for me not you." And we see that globalization has its unintended consequences, spreading disease and invasive species like a Biblical plague. Pesticides, now everywhere, are either deforming or de-sexing, and we can only wonder if chemicals are doing that to frogs, what are they doing to us, or more importantly, our kids?

There is an old John Prine song that puts a perspective on all this and our potential reaction to it. The chorus goes:

> "You can gaze out the window, get mad and get madder,
> Throw your hands in the air, say what does it matter.
> But it don't do no good to get angry, so help me I know.
> For a heart stained in anger grows weak and grows bitter.
> You become your own prisoner, as you watch yourself sit there,
> Wrapped up in a trap of your very own chain of sorrow."
>
> *—John Prine, "Bruised Orange (Chain of Sorrow)," Atlantic Records (1978)*

As amphibian biologists bearing witness to the sixth mass extinction (Wake and Vredenburg, 2008), we have to be careful not to lock ourselves down into some form of pre-clinical post-traumatic stress disorder. The world, whether it realizes it or not, needs us. My guess is that most of our angst does not come while doing fieldwork, but rather after we return. In the field (unless our study site has been ravaged), and right after we come back, we are dirty and itchy and maybe a little sore and bloodied, but happy and optimistic. We have seen our animals and they have shown something of themselves not seen before. Then we sit in our cramped little offices with our big flickering computer screens and we start to think. That's when the darkness creeps in (to paraphrase Greg Brown, 'People think small things when they stay too long in little rooms' ["One Night," Red House Records, 1982]), and that sets Prine's chain of sorrow reverberating between our amygdalas.

MJL at Boundary Waters northwest of Ely, Minnesota August, 2009.

There are ways to cope (humans are nothing if not adaptable). The technique used by U.S. G.I.s during WWII in Europe (although certainly combatants everywhere for all time have used it) went like this. Observing that soldiers obsessed with their own death often froze during combat, producing the thing they most feared, savvy G.I.s played a mind trick: they told themselves, "Screw it, I'm already dead, I just don't know where or when, and when it happens I probably won't even know it." And they became themselves again and they fought, and many of them lived to see VE Day. Understanding this, at some level biologists can find happiness knowing they are recording something that no one in the entire history of the universe may ever see again. Then, perhaps, a good thing happens: because they were themselves and because of their energy and efforts, the thing is preserved; because they persisted, that thing continues to live.

A second way to cope is even more desperate and epitomized by the New York City firefighters at the World Trade Center on 9/11 who went into the North Tower and up the stairs after the South Tower had already collapsed. As with the G.I.s, they must have thought, "I'm already dead." But unlike the G.I.s, they probably also thought that today, maybe this very hour, was the time they were going to die. They went up anyway, and to hear stories, they were calm. Again, working with animals and ecosystems the experience is similar (although the extinction experience is happening to them, not to us; not yet). It is possible to know death is imminent and face it, head on. It is even possible to be calm while doing it. As Edward Abbey (1990) quipped, "When the situation is hopeless, there's nothing to worry about."

FIG. 1. Drift fence around Crawfish Frog (*Lithobates areolatus*) breeding wetland in southwestern Indiana. Twenty-five years ago, this area was an open pit coal mine, since filled and recontoured, then purchased by the state as a Fish and Wildlife Area. The property was re-planted to native vegetation and is being managed as prairie, including using prescribed burns, shown here, to control for herbaceous and woody invasive species. Crawfish Frog populations can be robust under these conditions.

The trick in all this is to not lament the loss, whether it be us or the things we love, but to get on with it, and to find energy; and rather than mourn what is no longer, try to celebrate those things that are or were. Easier said than done, and for people in certain sub-professions of our field this can be more than difficult. My friends who work in zoos and aquariums, especially those who run captive breeding programs, are particularly vulnerable. Much like neurosurgeons, their jobs are high stress—they fail to succeed and there are forever consequences. To the extent that I can (without having a job with these sorts of ramifications), I empathize. I understand their loss of hope, which can sometimes descend deeper, into a place that is much darker and from where it is more difficult to rise. These are people who, if they drink, drink faster and more than your average herpetologist, which is saying something.

What our friends need to understand is that the problem does not lie with them; it lies within the situation they find themselves in. If roles were reversed it would be us on the floor next to that barstool. We are asking them to be on the front lines of the sixth mass extinction, and we're not giving them the financial or emotional support they need. They are frazzled and fraying. It is easy for them to think they're alone, and following a loss, it's easy for them to despair. But their fight is our fight, and they need our help.

I have never been privileged to work on amphibians in any place that was anywhere near pristine (I cut my herpetological teeth in Iowa—surely one of the most ravaged landscapes on earth). The ecosystems of my youth were wonders of existence. Not in the sense of wonder applied to many natural places; instead, in the sense of "I wonder how any wetland can possibly persist here?" These places never elicited any human emotion faintly resembling hope. I was working inside the Ed Abbey quote of desperate situations with nothing to worry about. But things have changed in the Midwest, some for the better, and I write this now to encourage colleagues who are losing, or who have lost, hope. I write this to celebrate the things that still are, and for things that remain possible. Specifically, I offer three examples of ecosystems involving Midwestern amphibians that have turned around, or where animals have found a way around, when there was no sane right to expect they would. And as I conclude, I suggest a mechanism to celebrate the forms of life for which this world is no longer "meant for one as beautiful as you" (Don McLean, "Vincent," Madacy Records, 1971).

Case Study 1: Mine-spoil prairies.— From the perspective of habitat loss, surface coal mining is about as nasty a business as you will find. One of our study sites is situated on the eastern margin of the Illinois Coal Basin. Here, coal seams lie about 30 m below the surface, shallow enough to be mined using surface drag-line techniques and the world's largest shovels. Companies currently mining this coal include Peabody, Foundation, Alliance, Armstrong, and Patriot. Surface coal mines are gigantic open pits with no recognizable ecology (except, perhaps to a microbiologist). Surface coal mining has taken place in our region for nearly a century, largely unregulated. Then, in 1977, the U.S. Federal Surface Mining Control and Reclamation Act became law. This legislation required that companies re-contour the landscape, replace topsoil, and re-vegetate. Our study site, 729 ha, was mined from 1976–1982, then reclaimed (Lannoo et al. 2009). It was re-vegetated by Peabody to non-native herbaceous vegetation (using the least expensive seed sources possible, for example, tall fescue, bush clover, and smooth brome). Then, in 1988, this land was purchased by the Indiana Department of Natural Resources, and land managers (two in particular, Ron Ronk and Randy Millar) have been eliminating non-native herbaceous plantings, replacing them with native grassland species, and instituting burning regimes for prairie maintenance. Using these processes they have created what we term mine spoil prairies. Reclaimed mine spoil prairies are not restorations *per se*, as these areas were not extensive grasslands at the time of European settlement. Instead, their history was primarily deciduous forest with scattered prairies, cleared for agriculture, and then dug for coal before being reclaimed.

During the first two field seasons of a large study designed to understand the biology of Crawfish Frogs (*Lithobates areolatus*), my graduate students Nate Engbrecht, Jennifer Heemeyer, Vanessa Kinney, and I captured or encountered an astonishing total of 33 amphibian and reptile species on this reclaimed coal spoil prairie, including two State Endangered species (Crawfish Frogs and Kirtland's Snake [*Clonophis kirtlandii*]) and three species of Special Concern (Blanchard's Cricket Frogs [*Acris blanchardi*], Eastern Box Turtles [*Terrapene carolina*], and Rough Greensnakes [*Opheodrys aestivus*]. We found 12 new county records (Lannoo et al. 2009; Kinney et al. 2010). Given the environmentally destructive reputation of surface coal mining, and the negative impacts that coal mining has had on amphibians, it is startling to

FIG. 2. (**left**) Male Crawfish Frog (*Lithobates areolatus*) captured in a drift fence/pitfall trap array after leaving its breeding wetland. FIG. 3. (**right**) Neotenic Eastern Tiger Salamander (*Ambystoma tigrinum*) viewed along the bottom a freshwater reservoir at Badger Army Ammunition Plant, near Baraboo, Wisconsin, USA.

know that such a richness of amphibian and reptile species could exist on a mine spoil prairie. The diversity of amphibians at our study site today exceeds that of Kankakee Sands, a restored native prairie 150 km north, despite the fact that 25 years ago our field site was an open pit mine, supporting no ecosystem that any vertebrate, or vertebrate ecologist, would recognize. Regional reptiles and amphibians were abundant enough, and occupying landscapes connected enough, that 33 species found their way to this new ecosystem without anybody's help, or in fact, anybody noticing.

Case Study 2: Cannibal Morph Eastern Tiger Salamander Wetlands.—In 1981, working in the region of northwestern Iowa called Okoboji, I discovered cannibal morph larvae in Eastern Tiger Salamanders (*Ambystoma tigrinum*). At the time this observation was publication worthy (Lannoo and Bachmann 1984) but no big deal, because Eastern Tiger Salamanders and western Barred Tiger Salamanders (*A. mavortium*) were considered the same species (*A. tigrinum*), and cannibal morph larvae were well known from Barred Tiger Salamander populations. But today, Eastern and Barred Tiger Salamanders are considered separate species, and these Eastern Tiger populations host the only known animals that express the full cannibal morphology (large, wide heads and hypertrophied teeth). As such, I've always thought they deserve federal protection under the Endangered Species Act as a Distinct Population Segment.

At the time of this discovery, the effects of early twentieth century swamp busting efforts were no different in Okoboji than anyplace else in the Midwest, and the habitats available to Tiger Salamanders had been reduced to four wetlands and associated uplands in Gull Point State Park, the Nature Conservancy's Frieda Haffner Kettlehole, and a smattering of public or private semi-permanent wetlands that may or may not have held water, depending on the phase of the hydrologic cycle.

Then, beginning in the late 1980s and early 1990s, the U.S. Fish and Wildlife Service, through its Waterfowl Production Area (WPA) program (http://www.fws.gov/refuges/whm/wpa.html), and with help from the Iowa Department of Natural Resources, Ducks Unlimited, Pheasants Forever, and other groups , began purchasing land in the Okoboji region—their goal was 30,000 acres. They broke tile lines to create wetlands and planted emergent rushes and sedges to facilitate restoration, and they seeded uplands to native prairie using local genotypes. This program continues, and if the acreage goal has not been met, they are close. Today, classes out of the Iowa Lakeside Laboratory can explore three massive, created grassland/wetland complexes (Spring Run, Welch Lake, and Excelsior Fen) in addition to the 160-acre native Cayler Prairie and its 200-acre annex.

The Okoboji region once supported a Northern Leopard Frog (*Lithobates pipiens*) frog leg industry that saw something like 20 million Leopard Frogs a year captured and shipped along railroads to restaurants as far east as Philadelphia (Lannoo 1996). This level of commercialization was, surprisingly, sustainable. What caused the Leopard Frog decline was swamp busting in the 1920s and 1930s, which eliminated ~98% of breeding wetlands. Today, due to the restoration efforts detailed above, there are likely more Leopard Frog populations on the Okoboji landscape than there have been since the early 1930s. There are also more Tiger Salamander populations, and I have found cannibal morphs in these new populations. While I still feel these animals should have federal protection, I am newly confident that barring some disease that affects salamanders the way *Bd* has affected frogs, that Eastern Tiger Salamander populations exhibiting cannibal morphs are secure, for the time being.

Case Study 3: A Neotenic Population of Tiger Salamanders at Badger Army Ammunition Plant.—In 1942, the U.S. Army purchased 30 km^2 acres of farmland immediately south of Baraboo, Wisconsin, near the region of Aldo Leopold's famous Shack, to create Badger Army Ammunition Plant, built to manufacture smokeless gunpowder. The Army erected scores of buildings and required a water source for, among

other things, fire fighting (as you can imagine given the nature of the enterprise). Two large reservoirs (4 million and 6 million gallons—envision large swimming pools) were dug at elevation into the south side of one of the Baraboo Hills, lined with concrete, and filled with fresh water. The smaller reservoir is chlorinated, and nothing much lives there. But at some point, breeding adult Eastern Tiger Salamanders began entering the larger reservoir. Following breeding, adults could not exit the reservoir to return to their upland habitats, because a 15-cm vertical lip extends from the water surface to the walkway. These adults likely died, as did any offspring that metamorphosed. But permanently aquatic animals could survive, and did, and this reservoir now supports a neotenic population of Tiger Salamanders. Mike Mossman of the Wisconsin DNR, Gary Casper of Great Lakes Ecological Services LLC, and the University of Wisconsin-Milwaukee Field Station, Steve Kimble at Purdue, several members of the Wisconsin DNR and U.S. Army, and I have been investigating the biology of this population, and the implications of the biology of this population. For example, what are the consequences in terms of gene flow and speciation to having a neotenic population of Tiger Salamanders embedded in a landscape matrix hosting metamorphosing populations of Tiger Salamanders? An interesting question addressing the response of an ancient genome to a recent anthropogenic change. Could anyone have imagined this amphibian response—a form of herpetological flipping the bird—to what most would consider a major environmental insult to the majestic Baraboo Hills?

In the first example, I note that one unintended consequence of restoring coal spoils to prairie is the proliferation of native amphibian and reptile species. In the second, I suggest that native amphibian populations respond well to intentional wetland restorations, and that rare phenotypes can be preserved. In the third, Tiger Salamanders, which surely must be among the most adaptable of all organisms, have turned the presence of a fresh water reservoir if not entirely to their advantage, not entirely to their disadvantage, and may have created a population spinning off onto its own evolutionary trajectory. All represent Midwestern examples of amphibian survival from an overly exploited landscape that give us hope.

I realize that for those amphibian biologists on the front lines, this will not be enough. Victories for populations of common, widespread species may not provide salve when dealing with extinctions of some of the neatest little animals anybody has ever seen. Why wouldn't we expect burnout and despair, and the sorts of behaviors in bars typically reserved for returning soldiers and off-shift firefighters? Again, these are people that need to know they're not alone, and that they have our support. I propose *Herpetological Review* erect a new section called "From the Ark," that both gives us a sense of the animals being captive reared and their status, and their stories—front line accounts from the fight to stop the sixth mass extinction. Such a section would allow for both sharing of stories—stories we need to know as they are happening—and perhaps some much-needed venting. These stories could publicize our cause to a much larger audience.

I close with another lyric from the folk tradition; this one from a guy everybody knows:

> "Yes, we made a promise we swore we'd always remember.
> No retreat, baby, no surrender."
> Blood brothers in the stormy night with a vow to defend.
> No retreat, baby, no surrender."
>
> (Bruce Springsteen, "No Surrender"
> Columbia Records, 1984)

Acknowledgments.—I thank Jim Murphy for the opportunity, and Joe Mendelson for several discussions of this topic; some in bars, some not. Gary Casper, Mike Mossman, Nate Engbrecht, Vanessa Kinney, Jennifer Heemeyer, Susie Lannoo, and Pete Lannoo read earlier drafts and offered comments.

Imperatives and Opportunities: Reformation of Herpetology in the Age of Amphibian Decline

Joe Townsend and I closed the final chapter of *Conservation of Mesoamerican Amphibians and Reptiles* (CMAR), published last year, with the following quotation from the chapter entitled "Exploration of a Little-Known Planet" in E. O. Wilson's masterful 2006 book *The Creation: An Appeal to Save Life on Earth*:

> "Despite the slow pace of exploration, biologists in the past two or three decades have found that Earth's biodiversity is disappearing at an accelerating rate, from habitat destruction, including habitat destruction now underway from climate warming, plus the spread of invasive species, pollution, and overharvesting. If these human-caused forces are left unabated, we could lose as many as half the species of plants and animals on Earth by the end of the century."

Taking E. O. Wilson's message to heart, Joe and I (Wilson and Townsend 2010:777) concluded that "Unless we act now, we [eventually might discover] that rationality provided us much better hindsight than foresight …"

Herpetologists have been slow to respond to imperatives facing the animals on which we work. As Joe Mendelson (2011) pointed out in his introspective essay, it was not until 1989 that "hallway conversations" at the First World Congress of Herpetology pointed to the possibility that amphibians might be in decline on a global scale. Two years later, David Wake formalized this concern with a paper in *Science* (1991). Since that time, however, global amphibian decline has become a hot topic, with attention given to this subject in a broad array of formats. Today, we have the Global Amphibian Assessment and its offshoots, including the GAA website, the AmphibiaWeb site, the seminal book by James Collins and Martha Crump (2009), and the conservation section in the *Journal of Herpetology*, to name a smattering of efforts to address this hugely important problem.

Much of the focus on global amphibian decline has been on the role of the chytrid fungus *Batrachochytrium dendrobatidis* (*Bd*; Longcore et al. 1999) in bringing about declines and extinctions among amphibian species, as evidenced in part by the Amphibian Diseases section in *Herpetological Review*. Bd is a major concern that must be controlled.

LARRY DAVID WILSON

e-mail: bufodoc@aol.com

PHOTO BY I. LUQUE-MONTES

LDW in Parque Nacional Cerro Azul Meámbar, Honduras, May 2008, with a *Mastigodryas dorsalis*, a Vulnerable species.

Unfortunately, the study of the ecology of this fungus with the hope of bringing it under control is not enough.

In light of the acknowledged impact of *Bd*, it is all the more significant an outcome of the Global Amphibian Assessment to declare that "Habitat loss and degradation are by far the greatest threats to amphibians at present, affecting nearly 4,000 species. The number of species impacted by habitat loss and degradation is almost four times greater than the next most common threat, pollution" (Stuart et al. 2010:13). This conclusion is consistent with those typically reached in environmental science and conservation biology textbooks. Evidently, the principal malfeasor for global amphibian decline is not *Batrachochytrium dendrobatidis*, but rather *Homo sapiens*. Humanity is the crux, both in the sense of "the basic, central, or critical point or feature" and "a puzzling or apparently insoluble problem" (American Heritage Dictionary, 3rd edition). At this point, the story becomes a constellation of problems so complicated that space here does not allow for a full elaboration of the causal labyrinth. My intention is not to rehash this story, because it appears as a series of recommendations in the closing CMAR chapter (Wilson and Townsend 2010:774), among other places in that volume. Nonetheless, we indicated that "Any serious, long-term approach to issues relating to conservation biology must be predicated on the understanding that biodiversity decline ultimately is created by uncontrolled human reproduction as measured against a fixed planetary resource base, which has produced an unsustainable existence for our species … ."

Apparently, we have entered an era in which our effort to control the planetary resource base is boomeranging on us. A few hours spent with any good environmental science text will justify this statement. We have entered into the Age of Environmental Superproblems (Bright 2000). As noted by Wilson and McCranie (2004: 13), this term is used to "describe environmental synergisms resulting from the interaction of two or more environmental problems, so that their combined effect is greater than the sum of their individual

effects. These problems represent an environmental worst-case scenario—the point when environmental problems become so serious that they produce unanticipated results, and a successful resolution threatens to slip forever from the grasp of humanity." In a sense, then, humanity has focused on the small picture to the point that the big picture has become even bigger—perhaps too big.

What humanity requires on a global basis is easy to state, but will be the most difficult cultural revolution ever undertaken by our species. The future human agenda must transform the emerging Age of Environmental Superproblems into the Age of Sustainability (Meadows et al. 2004). Sustainability often is defined as "The ability to meet humanity's current needs without compromising the ability of future generations to meet their needs" (Raven and Berg 2004:G-15). These authors also point out that "sustainability implies that the environment can function indefinitely without going into decline from the stresses imposed by human society on natural systems such as fertile soil, water, and air." The intent of this essay is not to detail how environmental sustainability can be accomplished; it is sufficient to say that it will involve creating a sustainable environmental footprint for humanity. Rather, its intent is to explore the role that the science of herpetology could and should play in the over-arching effort to achieve global sustainability.

Below are my suggestions for herpetologists to respond to the phenomenon of amphibian decline, and to transform the science into a force for achieving global environmental sustainability.

Transforming Pessimism to Realism.—I chose herpetology as my life work in that pivotal interval between undergraduate and graduate school. I credit Hobart M. Smith with helping me make that decision; his example as a herpetological speed demon and his counsel as a caring mentor pulled me away from ichthyology and pushed me into my eventual career. Hobart Smith's interest in the American tropics, especially Mexico, also became my interest. Years later, I visited Latin America, at the invitation of the late Ernest A. Liner, who then became another influential mentor. I briefly referred to that life-changing trip in my contribution to the remarkable seven-page obituary of Ernie that appeared in this journal. The following year, I accompanied John R. Meyer on a three-month sojourn to Honduras, an experience that 44 years ago set the hook for my career. During this time, there have been highs (the discovery of new species and the continuing series of publications about what we found) and lows (the specter of advancing habitat degradation and loss, the unexplained disappearance of once-plentiful streamside frogs, and the widespread calamitous damage done by Hurricane Mitch). Like Joe Mendelson, I also experienced the apparent loss of species my coauthors and I described, indeed one of the toughest blows a taxonomist can bear. In the face of the lows detracting from the highs, it would be easy to give up and move on to other pursuits. In this connection, I received the latest, heroically redesigned issue of this journal in which Jim Murphy, in the Zoo View section he edits, included a short piece entitled "Hopelessness" that remarked about "a continuing culture of despair" among conservation biologists, especially younger ones, who are bemoaning the absence of a message of hope in what they are hearing at conferences. Upon reading Jim's commentary, I was reminded of something Joe Townsend and I wrote in the concluding CMAR chapter (p. 777): "The extinction cycle described by conservation biologists … will assume tornadic dimensions, sweeping life's diversity into an ever-widening and ever more rapid spiral, leading to a crescendo the likes of which has not occurred on our planet since the close of the Cretaceous, which marked the most recent mass extinction episode." Had we ended the chapter on this point, we could have been accused of contributing to "the culture of despair." However, we went on to say (p. 777) that "Given our conclusions, three major approaches seem possible. Some people, the pessimists among us, will look at what we have written and decide that the conservation agenda will never be accomplished, no matter what is done. Other people, the optimists around us, will think that everything will turn out just fine, whether conservationists do anything. Neither of these approaches can be expected to move the conservation

agenda forward. The beliefs of both the pessimists and the optimists rob them of any opportunity to participate meaningfully in the process of designing workable solutions to the problems we face. Thus, it is left to the realists to assess any given situation or problem and design solutions that deal with things as they actually are, instead of how we wish them to be. This realistic approach marks the contributions to this volume."

Unfortunately, we need to hear the bad news to wake us out of our complacency, but if that is all we hear we are not stimulated to make things better. Giving up is easy, which is what the pessimists *and* optimists do. The work begins when the realists recognize where events seem to be heading, decide these trends are undesirable, and commit to the demanding, perhaps life-long task to make things better. So, the picture for conservation biologists is bleak, but if we give up, the outcome is determined. Instead, if we devote our time toward making the world a better place than when we arrived (in my case, when the world was embroiled in WWII), then the outcome becomes shaped by our efforts.

Reconceptualizing Herpetology.—Back in the early 1960s, when I was saddling up for graduate school, I thought the going would be rough but that trail's end would be rosy. I thought I would be doing what I enjoyed and get paid for it, too. The person I am today might think that young guy from the Great Corn Desert of central Illinois was a tad naïve, but it turned out that I had the opportunity to work with "my critters" while making a reasonably comfortable living. In retrospect, my study program was designed for a world that was fast disappearing. Had my instructors known then what I know now, that program might have been much different. My comments are meant primarily for the field herpetologist, but in my mind herpetology begins and ends in the field. Furthermore, the "field" turned out to be Mesoamerica, principally Honduras. Pretty much by accident, I became interested in a socioeconomically underdeveloped area with a rapidly-growing human population competing for habitat with the members of an imposing, diverse herpetofauna characterized by high endemism. This description of the Honduran herpetofauna would not have applied to the Honduras I entered in 1967, because in the interim the known herpetofaunal diversity in the country has just about doubled and the percentage of endemicity has become the highest in Central America (Wilson and Johnson 2010).

If I could design a modern program for graduate study, it would have to be grounded in the principles of environmental science and conservation biology. No matter where one's research interests might lead, they will be pursued against a backdrop of humanity's impact on the natural world. In his thought-provoking piece, Joe Mendelson (2011:22) opined that "There no longer exists a natural upland ecosystem in Mesoamerica." Although, in context, the statement is startling, it, unfortunately, is not surprising to anyone who has spent time working in this region. I first went to Honduras in 1967, and it took me two weeks before I found my first snake; unlike Joe Mendelson, I cannot claim that my lack of early success was due to the unexplained disappearance of my target animals. We did not describe our first new species in the country, *Leptodactylus silvanimbus*, until 13 years later (McCranie et al. 1980). We found the first specimen of that species *under a log in a pasture* cut out of cloud forest! For us, this came to be the rule rather than the exception. So, if one is interested in working in a natural ecosystem (i.e., one undisturbed by humans), one is in for a long hunt because in the age of global environmental problems (e.g., global climate change), there are only various approximations to natural ecosystems anywhere on Earth. That such is a given is evident by the lack of a warning in herpetological publications, similar to those on cigarette packages, that "This study was conducted in a disturbed ecosystem."

The next most important area to explore would have been the language, political science, and cultural history of my chosen region of study: Latin America. I would have reached that region better prepared to understand the people.

A lot more is involved with this story, but suffice it to say that real success is gained by never giving up, having the most destination-specific educational training, and coming to understand that people everywhere have similar goals and aspirations. For herpetology to have a meaningful role in human affairs, students will have to learn about the realities posed by life in the 21st century. They will need to understand the imperatives all humans face, and how these imperatives will shape the opportunities that will exist for herpetologists.

Imperatives and Opportunities for Fieldwork.—The imperatives are evident to those who wish to learn the "big picture;" the opportunities are what we wish to make of them. What follows are some of the ideas I gained over the last four and one-half decades on conserving the creatures we study.

Permits to work in foreign countries have become *de rigueur*, which is the imperative; the opportunity is to understand the operation of the permitting agency, to earn the confidence of its personnel, and to use whatever resources one has to contribute to the success of this agency. At a minimum, this last effort should include the submission of a detailed report on the findings, in the language of the host country (our 2010 Honduras project report, incidentally, was publicized recently in a long article in *La Tribuna*, one of Honduras' major newspapers). In addition, contributions can be made to agency efforts to publicize their work through posters and and other methods.

Permits provide a means of introduction to local people, including protected areas personnel (including those of involved NGOs) and community leaders; up-front explanations of the goals of the projected work help gain access to areas of interest, provide assistance and training opportunities on site, and, ultimately allow reporting the results of the work to those same stakeholders, including educators, schoolchildren, and print and TV journalists, with the help of the local people who were on the trip (e.g., *guardarecursos*). Therein lies both the imperative and opportunity.

In planning for fieldwork, look farther afield than in the past, because opportunities lie in such previously unsurveyed areas. For example, much has been made of the species richness of the Quebrada de Oro area of northern Honduras and its subsequent decline (McCranie and Casteñeda 2007; McCranie and Wilson 2002; Wilson and McCranie 1998). A number of endemic amphibians were thought to have disappeared from this area, and some have been presumed to be extinct. Recent work, however, in another area of the long Cordillera Nombre de Dios has allowed for reassessment of the conservation status of some of these heretofore-thought-to-be-absent amphibians (Townsend et al. 2011; Townsend et al., *in press*), including *Plectrohyla chrysopleura* and *Duellmanohyla salvavida* (Figs. 1 and 2). A similar example involving *Plectrohyla hazelae* was reported in the previous issue of this journal (Heimes and Aguilar 2011). These examples, along with that of *Incilius holdridgei* (Abarca et al. 2010), give us good reason to expect that others will also reappear.

The necessity to return to the capital of the country in question to obtain export permits and the like is yet another imperative that provides other opportunities. Such a requirement can allow for meeting with local biologists at colleges and universities for strategy discussions, content presentations, and development and maintenance of other longer-term associations, such as cooperative appointments (see my address above) and meeting organization. Promising local young biologists also turn up at such times, providing the chance to help further their education in one's own country. This accounting of the opportunities offered while "in country" just scratches the surface of what is limited only by imagination and commitment.

Since herpetologists are the ones who discovered that "their animals" are in decline, their research priorities can be reconfigured to include studies that determine the conservation status of the target organisms and highlight the herpetofauna of existing and proposed protected areas, as we are doing in Honduras (e.g., Townsend and Wilson 2008; Townsend et al., *in press*). Increasing the accessibility of this information can be accomplished by presenting scientific results either in a bilingual format (Townsend and Wilson 2008) or in the language of the residents of the area in question (e.g., Wilson et al., *in press*), or better yet, through dissemination of results to the general public through local media outlets and public presentations.

A Final Imperative and Opportunity.—That human beings are responsible for almost all environmental problems, including those of interest to conservation biologists, is a virtual given (Wilson and Townsend 2010). However, the scramble to determine the role of *Bd* in the global amphibian crisis almost has quarantined the attention of herpetologists searching for answers to the causes of this crisis. In my opinion, another of the basic rules of environmental science has been lost in the shuffle…sort of. This is the simple rule that in nature everything is connected to everything else. This statement also applies to the human world and its relationships with the natural world; humans are, after all, a product of the same processes that created the natural world. For herpetologists, the implication should be obvious. Although not yet officially tabulated to the extent done for amphibians, the reptiles, our *other* group (of course, including turtles and crocodilians, but excluding the feathered ones) is also in decline. While awaiting the Global Reptile Assessment, the contributors to CMAR conducted their own assessment of the conservation status of Mesoamerican reptiles (in addition to the amphibians), with the results summarized by Wilson and Townsend (2010), who concluded, using their Conservation Status Scores, that of 1139 species of reptiles scored, 966 (84.8%) fell into their very high category of conservation significance. With respect to the individual orders, only crocodilians, of which there are three species in Mesoamerica, had less than 80% of the constituent species in the very high category, based largely on their comparatively broad distributions. A higher percentage (93.0) of amphibians fell into the very high category, especially because of the scores for salamanders, but this indicates that amphibians are only slightly worse off than reptiles. Thus, it appears that another imperative faces herpetologists, especially those working in Mesoamerica, presenting another array of opportunities. So, how long will we have to await a Global Reptile Assessment? More to the point, how long will the reptiles have to wait to be given their fair measure of attention?

Acknowledgments.—I appreciate Jim Murphy asking me to write this essay. I am indebted to Louis W. Porras and Josiah H. Townsend for their extremely helpful counsel as this essay took shape. I also wish to thank Ileana R. Luque Montes for the use of the photo of me and J. H. Townsend for the use of the photos of the frogs that accompany this work.

Herpetology at a Biogeographical Junction: Research and Teaching at the Hebrew University of Jerusalem (Israel)

The herpetofauna and herpetology are particularly attractive in the southern Levant, the southwestern tip of the "fertile crescent." This area, historically known as Palestine and now shared by Israel and Jordan, serves as meeting arena for faunal elements from Africa, Asia, and Europe (Bodenheimer 1935; Por 1975) and the local herpetofauna is heterogeneous and rich in accordance (Disi 1996, 2002, 2011; Haas 1952a; Werner 1988). Herpetology is attractive here not merely because the species are ample and the open questions endless. Rather, mesic Mediterranean, semi-arid Irano-Turanian, arid Arabian and Saharan, and Afro-tropical ecosystems, and their assorted interactions, are all accessible at short range, by good roads, from universities. Moreover, a country-wide network of some twenty field schools and research stations provides bases for local research. The oldest university is the Hebrew University of Jerusalem, established in 1925. Its zoological collections were started earlier, as told below. It has a history of ramified herpetological research, especially collection-based but also in the field.

YEHUDAH L. WERNER
Department of Evolution, Systematics and Ecology
The Hebrew University of Jerusalem
91904 Jerusalem, Israel
e-mail: yehudah_w@yahoo.com

History of the collection.—The Hebrew University's collection of amphibians and reptiles was started by Israel Aharoni before the university was even conceived. Aharoni, born in Lithuania in 1882, was studying Zoology and Semitic

FIG. 1. Israel Aharoni teaching about Palestine's vertebrates, 1941. The blackboard carries names and terms in Arabic, Hebrew, and Latin.

PHOTO BY NAHUM TIM GIDAL, COURTESY OF THE HEBREW UNIVERSITY OF JERUSALEM

languages in Prague until in 1901 he immigrated to the Palestinian province of Syria within the Turkish Empire. Residing at Rehovot and Jerusalem and teaching school, he continued to privately learn zoology and started to investigate the local fauna. Gradually he amassed collections of various groups from Palestine and adjacent areas, often assisted by Arab hunters, and became a knowledgeable and renowned animal expert, specimen supplier to institutions abroad, and Hebraist (Leshem 2000).

Soon after the opening of the Hebrew University of Jerusalem on Mt. Scopus in 1925 (under the British Mandate of Palestine), its head of Zoology, F. S. Bodenheimer (1897–1959), recruited Aharoni to teach vertebrate zoology. He came with his collections (those not earlier deposited in Palestinian clerical establishments or European museums and universities), including a significant reptile collection (Bodenheimer 1959). Specimen data tags, however, though commonly present, were often too generalized (e.g., "Syrian desert") or referred to Aharoni's location when receiving them from collectors (e.g., "Rehovot" for desert lizards). Cataloging the collection was later undertaken by his daughter Bat-Sheva Aharoni. The university, presumably regarding animal-lore as inferior, allotted to this treasure a humid cellar (Jacob Wahrman, pers. comm.). Gradually the collection grew through the additional activity of faculty (especially G. Haas) and students (especially H. Mendelssohn and H. Steinitz).

Aharoni was an enthusiastic teacher (Fig. 1). His textbook on the country's reptiles (Aharoni 1929) was pioneering in coining Hebrew species names, besides including interesting biological observations and eclectic anatomical details. It also bore witness to the collection having contained some representation of Europe's herpetofauna. Aharoni's book includes some European species, notably *Lacerta agilis,* ostensibly as part of the local fauna; this has been explained as probably resulting from his having had a jar with European material on his desk when writing. Aharoni succumbed to a heart attack in 1946.

The war of independence (1948–1949), while establishing the state of Israel, left the Mt. Scopus campus, Israel's university, as an Israeli enclave locked within Jordanian-occupied territory. Libraries and collections were held hostage on the campus; Jordan forbade their evacuation. Until June 1967 the Israeli garrison was replaced every fortnight through a UN-supervised convoy of armored cars traversing the Jordanian territory. Each convoy carried also supplies for a fortnight.

A few Hebrew University representatives were permitted to participate in order to inspect and care for the cultural treasures on the mountain, susceptible to shooting from the outside and vandalism on the inside. This was an adventurous mission for the staff. The Jordanians would inspect the returning cars and people's bags for items smuggled out but refrained from bodily search. So in all weather the staff wore coats, ascended slim and descended obese, with books tucked in belts, large preserved snakes strapped across

breasts, and small specimens filling pockets and specially contrived carton receptacles strapped to shins under long pants.

By this and other means the Department of Zoology's reptile collection was gradually growing in its temporary home, tall wood cabinets along one wall of the spacious office of Dr. Georg Haas (Fig. 2), in the Italian Nunnery St Antonio College in Jerusalem's Talbiye quarter. Since 1950 this was the department's location, because the university, banned from its campus, was scattered throughout Jerusalem (see History of teaching). Haas (1905–1981; Werner 1982a, b), leading the development of this and some other collections, endeavored to include instructive exotic specimens. He cultivated international relations, arranged exchanges, and extracted donations. The amphibian collection was rather the project of Dr Heinz Steinitz (1909–1971; Boschwitz 1971; Kuehne 1972; Por 1973), otherwise ichthyologist, histologist, and experimental morphologist.

Meanwhile the young generation, led by Jacob Wahrman (1924–2005; Richler 2006), was conducting collecting trips all over the country, with emphasis on the poorly explored southern desert, the Negev. During the 1950–60s the Department of Zoology had two jeeps (one shared with the Department of Parasitology, Medical School). These served in trips planned to survey the country with a view to mapping species distributions. Many trips were systematically multi-purpose, with emphasis on trapping rodents (Zahavi and Wahrman 1957) but some were primarily herpetological. These survey efforts contributed much to the animal distribution maps in the Atlas of Israel (Wahrman 1970).

In 1965 the Department of Zoology and the Collections were moved from the Italian Nunnery to a group of buildings adjoining the Russian Compound (downtown) that had been evacuated by the Medical School, which moved to its

salem's western outskirts. Here the collections had their own separate masonry building and herpetology occupied two spacious rooms.

The collection today.—In 1985 the Department of Zoology moved to the HUJ sciences campus at Giv'at Ram, and its population-oriented staff and the collections moved into the Berman and Lubin buildings, evacuated by the Department of Psychology that had moved to the resurrected Mt. Scopus campus. The herpetological collection remains in the Lubin Building, occupying a hall housing the wet material and an adjoining work space housing also literature and dry specimens.

The collection comprises over 22,000 catalogued specimens of amphibians and reptiles, derived in principle from three sources. 1) Most specimens are from the "survey area," Israel with the Golan plateau, and Sinai. This is the most extensive regional record of Levant taxa. It is the world's only collection with the full Israeli herpetofauna, having the only two existing specimens of the extinct *Discoglossus nigriventer* (Fig. 3). It also includes one of the last local crocodiles. 2) Comparative material from surrounding countries. 3) Instructive material representing systematically or geographically important groups (e.g., *Sphenodon*). Recently the type material in the collection, 17 species and 23 subspecies, has been reported by Ben-Eliahu and Golani (2010a).

The bulk of the collection (85%) is in 75% ethanol (amphibians and geckos, 70%) denatured with 5% methanol, after fixation with formalin. In recent years fixation is preceded by taking tissue samples for DNA work. Because the collection is much used for research, specimens are individually tagged with their main data, and assembled in glass jars carrying the list of numbers. The jars are on open metal shelves. Large (75 liter) plastic "tanks" contain straight-fixed snakes and bulky specimens such as turtles. It is a local innovation that these tanks rest on individual wheeled bases and are on the floor under the jar shelves, from where they are easily rolled out (Fig. 4.).

The rest comprises stuffed or dry specimens, skeletons, and skins. A unique (largely uncatalogued) resource is a large collection of microscope slides, mainly of karyology, ontogeny, cranial morphology, and tail regeneration of amphibians and reptiles, from the work of several researchers. Since 1994 tissue samples from fresh specimens have been preserved separately for future DNA analysis (several hundred samples). Several hundred shed skins, feces, eggshells, and donated specimens await cataloguing.

In recent decades the sources of new material have been changing (Ben-Eliahu and Golani 2010b). The planned collecting trips have receded and ceased for both economics and conservation. Course field trips have stopped in 1999 upon the teacher's retirement. Currently an estimated annual average of 250 specimens come as vouchers from specific research projects or, mostly as roadkills, from the Israel Herpetological Information Centre (of the Society for the Protection of Nature in Israel), individual rangers of the Israel Nature and Parks Authority, students, and others, including herpetoculturists abroad.

Cataloging.—Before the computerization era, cataloging was retrieval-friendly through three devices. 1) The single set of serial numbers serving the whole collection is subdivided into sections for groups: 1–800, Amphibia; 801–1000, Chelonia; 1001–3000 Sauria; 3001–5000, Ophidia and 5001–7000

again Sauria, and so on. Each group is catalogued in a separate volume, so searching for a snake does not require leafing through all the frogs and lizards. 2) A card file of locality names, each card carrying the geographical coordinates, and a brief record of specimens from that locality. 3) A cross index by species on large durable cards. Entering specimens into both card indexes was discontinued when computerization started. The species index had been initiated by Jacob Wahrman, to whom the collection owes much of its professional 'law and order' spirit.

FIG. 6. "Historical" field trip of the faunistics course to the Negev (11 March 1963). Jacob H. Hoofien, invited to reinforce the staff as reptile expert, speaks to the students using an improvised board suspended on a jeep.

Computerizing the HUJ collections has been a chronic effort for some decades, involving trial-and-error with programmers and programs. Now, however, the herpetological catalog approaches completion and functionality in Microsoft's Excel.

Staff.—During 1953–1973 a student 'research assistant' (parallel to the teaching assistants), 18 hours/week, helped in the collection. In 1972 the Department of Zoology established the 'Zoological Museum' (a term later outlawed). The department's chairperson, Hefziba Eyal-Giladi, appointed Adam Ben-Tuvia (1919–1999; Golani 1999) as museum Director, and Yehudah Werner as Curator of Amphibians and Reptiles. From 1973, the university budget started to deteriorate. Since then, technical assistance in the herpetological collection diminished to an on-and-off basis, with expectable consequences. In 1999, upon the mandatory retirement of Curator Werner, a part-time collection manager was appointed—Naomi Sivan, MSc, formerly Werner's academic technical assistant and research associate. But she was soon replaced (on budget grounds) by Boaz Shacham, then BSc. Recently the collection's research capacity has been reinforced by the appointment of a Research Associate, Hervé Seligmann.

Research.—The collection has been serving research by staff, research students, student course-projects, visitors, and investigators abroad (through lending). The local research goes far beyond the classical issues of systematics (e.g., Werner et al. 1999) and distribution (e.g., Werner 1987). Subjects have ranged from developmental morphology (e.g., Eyal-Giladi 1964) through polymorphism (e.g., Shacham 2004), functional morphology of tails (e.g., Werner 1961, 1968), eyes (e.g., Werner and Seifan 2006), and ears (e.g., Werner et al. 2008) to longevity (e.g., Werner et al. 1993) and reproductive biology (e.g., Frankenberg and Werner 1992a). In addition, the collection houses the voucher specimens of projects from cephalic anatomy (e.g., Haas 1973) to auditory physiology (e.g., Werner 1972).

Current research includes the northwards penetration, along the Jordan Valley, of lizards and snakes from the Negev Desert (Shacham et al. 2009); identification and distribution of some *Acanthodactylus* lizards (Werner); sexual dimorphism in snakes with emphasis on eye size (Werner, Babocsay [Budapest], Faiman [Parasitology], Razzetti [Pavia], and Seligmann); sexual size dimorphism in Israeli snakes (Werner and Ventura); size variation in Israeli tortoises and the identity of *Testudo floweri* (Meiri, Itescu, H. Shacham, and Werner); sizes of parietal eyes in lizards (Labra [Oslo] and Seligmann; Labra et al. 2010); left-handed *Sphenodon*s grow more slowly (Seligmann, *in press*); error coordination between codon-anticodon mismatch and tRNA misacylation decreases developmental instability in lizards (Seligmann); and off-frame stops increase developmental stability (Seligmann).

Field research, in addition to leading or aiding routine conservation-oriented surveys, focused in recent years on the foraging mode of geckos. Several projects explored the synergism of the many factors modulating the foraging activity pattern (e.g., Werner et al. 2006; Seligmann et al. 2007).

Teaching.—Teaching herpetology at HUJ has comprised an undergraduate course, a graduate course, field trips, and student projects at all levels. All these have interacted with the collection, although for the courses a designated teaching collection also exists.

History of teaching.—With the redeployment of the HUJ after the 1948 War of Independence, its teaching was resumed in rented quarters scattered throughout Jerusalem. Biology was studied directly towards the MSc and comprised one major and two minors, such as Botany with Zoology and Biochemistry or Zoology with Botany and Parasitology. Since Israel Aharoni had passed away in 1946, "Faunistics" was taught throughout the 1950s by Heinrich Mendelssohn, fortnightly visiting from the Biological-Pedagogical Institute of Tel Aviv (Fig. 5).

FIG. 7. The two historical specimens of *Testudo kleinmanni* that were found separately on 11 March 1963, photographed in the lab (left, ventral aspect).

After some provisional locations, by 1950 the Departments of Botany and Zoology had settled in a wing of the Italian Nunnery St. Antonio College in Jerusalem's Talbiye quarter, where Georg Haas (Werner 1982a, b) and others endeavored to assemble new collections. By 1963 when Mendelssohn, tired of travelling to Jerusalem, resigned, the collections could already provide specimens for demonstration. A year-long lecture course was developed, obligatory for all 120 Biology sophomores: one semester vertebrates (headed by G. Haas), one semester invertebrates, including entomology. Haas opened the herpetology chapter saying Israel harbored 40 species of lizards, 33 snakes, and four non-marine turtles (a recent count had 44 lizards and 44 snakes; Werner and Sion 2008).

The course included field trips. One of the first of these yielded the re-discovery of the Egyptian Tortoise, *Testudo kleinmanni*, in Israel. Its occurrence had been reported in the older literature ("Testuco leithi," Lortet 1883; Tristram 1884) but in the intervening decades even targeted quests had failed to find it. It took the combination of numerous searchers and correct season and weather to find it in the northern Negev sands ("14 km S of Beer Sheva") on 11 March 1963 (Figs. 6, 7). Later the Israeli population was defined a separate species, *Testudo werneri* (Perälä 2001), but this has since been contested (Široký and Fritz 2007).

The BSc course.—In 1967 the Life Sciences Institute was founded, comprising the departments of Biochemistry, Botany, Genetics, and Zoology. Thereupon BSc studies were established, and the mandatory faunistics course was subdivided into four elective one-term fauna courses accompanied by a mandatory common course on shared principles (it soon became a biogeography course), all in the third year. Among the four courses, "Introduction to the Knowledge of Amphibians and Reptiles" was somewhat unique in its integration of different zoological disciplines, from chromosomes to thermoregulation, leaning on teacher's research experience (Werner 2004b, 2005). Fig. 8 shows the course's view of the

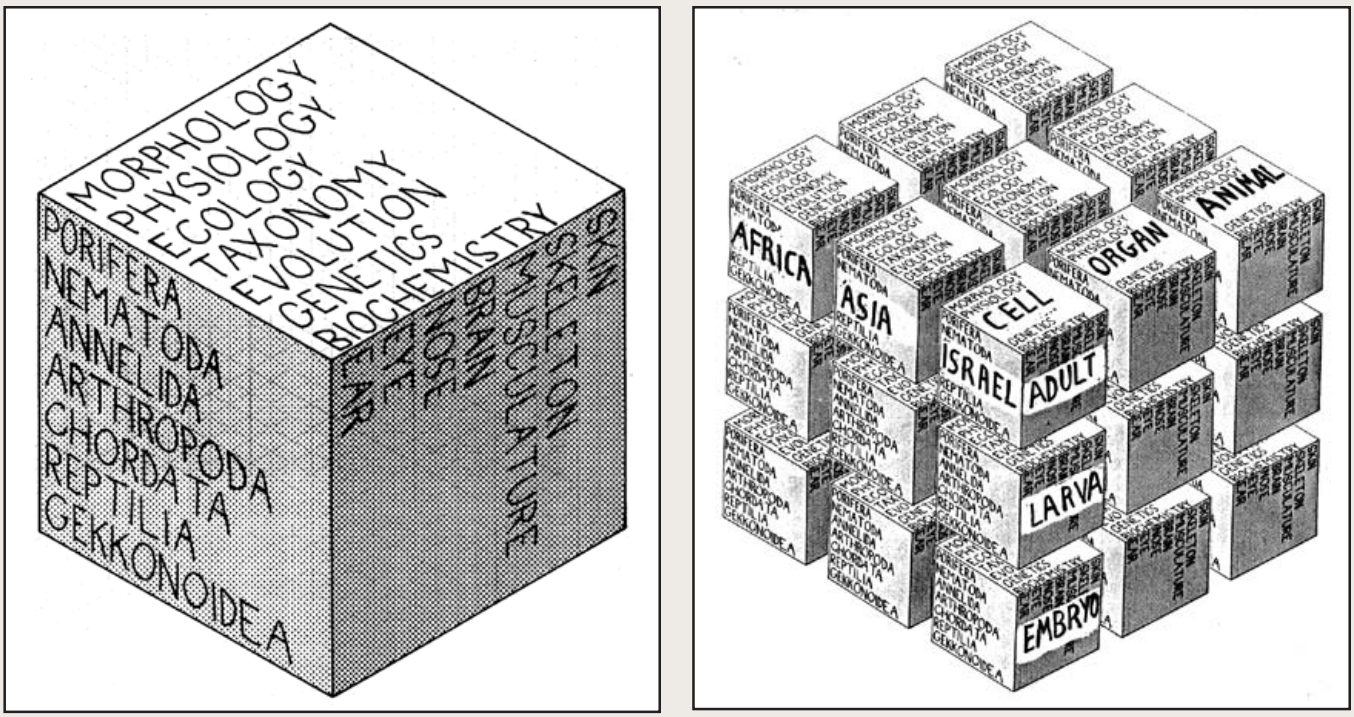

FIG. 8. Scheme of the composition of zoology. A) Primary cube showing three main dimensions: discipline, organ system, systematics. Journals exist for all subdivisions, and most internal intersection cubes exist (e.g., physiology of eye of reptiles). B) Additional dimensions require piling copies of the primary cube: geography, organization level, ontogenetic time. The last can be replaced with paleontological time. In each dimension, only a few units are shown as examples. Herpetology is conceived as intersecting and including all six other dimensions.

FIG. 10. Dror Hawlena (sitting) explains pitfall-trap operation to students of Ben Gurion University of the Negev, Western Negev desert, Israel, 1999.

multi-dimensionality of zoology and hence of herpetology. A typical five-hour session presented both some Israeli taxa and some natural history topic(s), preferably matched, such as systematics of lizards, and tail regeneration. Course activity comprised teacher's lectures, students' proseminars, individual lab work, and museum-style 'demonstrations.' Field trips included meeting the species, comparing the habitats, and experiencing field methods. In later years, transportation expenses constrained the course to 17 students. Usually it was full, occasionally including a student from another university, a schoolteacher on study leave, or a zoo staff member.

The MSc course.—Among the fauna courses, only in herpetology was a viable MSc course developed, "Herpetology for Advanced Students," starting in 1975–1976. Following initial experimentation with contents, it comprised a planned symposium-like journal club, and individual research projects planned for potential later merging. Some of these student projects (mostly partly collection-based) were published (notably Perry et al. 1990). This course was normally given every other year to 5–7 students, in alternation with moderately reptile-biased 'Projects in Comparative and Functional Morphology'.

The field trips.—The field trips of the two herpetology courses were sometimes held together (Fig. 9). The BSc students emphasized acquainting themselves with species, habitats and methods but the MSc students mostly collected data for their projects. Initially we depended on the collection to know and plan in advance what the students could encounter everywhere; later (with budgets dwindling) the course field trips became research expeditions planned to fill data (and specimen) voids, so that students shared the experience of discovery. In the 1990s students increasingly opposed the collecting of specimens. We discussed the difference, even clash, between conservation and avoidance of cruelty to animals, and the conservation role of collections through the clarification of biodiversity.

Other student projects.—Many BSc student research projects within the frames of other courses (mainly but not only Prof. J. Heller's systematics course), were carried out in the herpetology collection. Typically these were performed by a team of two or three students, each reporting on her or his share (e.g., comparing meristic, respectively mensural, characters in two lizard samples) towards later merging. Several of these were published (respectably), including descriptions of new taxa. One of the first projects made the Biological Reviews, Cambridge (Wolf and Werner 1994).

Theses.—In the course of time, many morphological, developmental, and especially comparative-anatomical MSc or PhD theses on amphibians or reptiles, and some on their behavior, have interacted with the collection to varying extent. These included for example the MSc theses of Zakbach (1939), Eyal-Giladi (1949, 1964), Nevo (1957), Stettiner-Kallner (1958), Ginzburg (1965), Frankenberg (1972), Shy (1978), Bouskila (1984), Shani (1990), Por Efrati (1991), Bogin (1999), and Shacham (2004), and the PhD theses of A. Moscona (1950), H. Moscona (1950), Feldman (1952), Boschwitz (1958), Werner (1961), Kochva (1962), Nevo (1964), and Frankenberg (1978). The PhD of Seligmann (2003), 99% collection based,

has significantly impacted the field (e.g., Lachman et al. 2006). One foreign student obtained his PhD here (Babocsay 2006). Additionally, the collection has occasionally served in the MSc theses of students from other Israeli universities.

Outreach.—Questions from the public and especially herpetology students, often by e-mail from neighboring countries, are regularly answered. Groups of visitors to the collection are introduced to reptile biology and its research. During 1982–1998, and again in recent years, the staff has been playing a leading role in organizing national herpetological symposia ("study days") for the general public, including rangers, inspectors, teachers, students, amateurs, and others.

Prospects.—With the (mandatory) retirement of Werner in 1999 the teaching activity (not the research) has largely abated. However, currently one PhD student and one MSc student work respectively on behavioral ecology and reproductive ecology of geckos. The collection is now poised to receive a new curator. Thanks to the appointment of Dror Hawlena (Fig. 10), presumably the educational activity will soon be revived and rejuvenated.

Acknowledgments.—Grateful credit is given for photographic contributions by Nahum Tim Gidal (courtesy of the Hebrew University of Jerusalem), Nurit Werner, Jacob Wahrman, and Amos Bouskila. I thank Boaz Shacham for updated information on the collection under his care.

Ecological Consequences of Continual Volcanic Activity on the Lizard, *Anolis lividus*, from Montserrat

Understanding the effects of environmental disasters on ecosystems and mechanisms of ecological recovery is a central pursuit in biology. Acute episodes, such as tsunamis or volcanic eruptions, can decimate entire ecosystems, but research has shown that recovery from single devastating events can prove to be rapid. For example, following the destructive eruption of the Krakatau islands in Indonesia in 1883, which left its land and associated waters completely sterilized, both the terrestrial and marine life rebounded quickly (Barber et al. 2002; Dammerman 1929; Thornton 1996). Furthermore, under certain conditions ecosystems can prove to be resilient to environmental devastation. For example, corals growing on hard substrate, such as rock, were largely unaffected by the tidal waves of the tsunami in Aceh, Indonesia in 2005, whereas corals growing on rubble and sand, and their associated communities, were devastated (Baird et al. 2005).

Many contemporary environmental disasters occur continually, and require that ecosystems respond to recurrent assault. Beginning in 1995 the island of Montserrat in the West Indies has suffered acute and persistent volcanic activity from the Soufrière Hills Volcano (Robertson et al. 2000). The most devastating volcanic events are pyroclastic flows, or high-speed currents of rocks and gas resulting from dome collapse, and periodic ash clouds composed of volcanic gases and particulate matter (Montserrat Volcano Observatory Team 1997; Fig. 1). There are also periodic landslides termed lahars that deposit meters of pyroclastic material into the river valleys, and acid rain that affects the areas closest to the volcano. These events occur regularly and are undoubtedly traumatic to the Montserratian ecosystem, particularly in communities in the southern half of the island, where volcanic impact is more severe and continual. Knowledge of how persistent volcanic activity affects the island's endemic flora and fauna can inform efficient conservation efforts, but little is currently known.

FIG. 1. View of Plymouth, the defunct capital, where *Anolis lividus* was once quite abundant, as seen from the sea following the January 2010 dome collapse.

Research has shown that the long-term effects of the volcano on local wildlife can be severe. For example, despite intense sampling, many endemic coleopteran species have not been captured since volcanic activity began (Marske et al. 2007). Furthermore, the rare endemic oriole, *Icterus oberi*, is in imminent threat of extinction (Lovette et al. 1999). More than half of the oriole's habitat has been destroyed due to eruptions from the Soufrière Hills (Hilton et al. 2003), while periodic ash episodes further deplete populations and nesting sites (Dalsgaard et. al. 2007). The endemic galliwasp, *Diploglossus montiserrati*, was commonly found before the eruption of 1995, but only a handful of individuals have been captured since, despite extensive sampling by the Department of Agriculture (G. A. L. Gray, pers. comm.). And while efforts are focused on the northern half of Montserrat, even

less is known about populations in close proximity to the volcano, especially in the permanent exclusion zone of the island, where human traffic is prohibited.

Beginning in 2009 we have been monitoring populations of the endemic anole, *Anolis lividus* (Fig. 2), both in the safe zone (northern Montserrat) and in the permanent exclusion zone (southern Montserrat). In comparison to many other reptiles and amphibians on the island, much is known about the biology of *A. lividus*, such as its natural history (Lazell 1972; Schwartz and Henderson 1991; Underwood 1959; Williams 1962), malarial parasites (Staats and Schall 1996), and evolutionary relationships (Losos and Thorpe 2004; Schneider et al. 2001; Thorpe and Malhotra 1996). Despite more general knowledge of the species, there has been no assessment of how populations have been affected by volcanic activity until now. We present the first field observations of lizard habitat conditions from six sites within the permanent exclusion zone in southwestern Montserrat. The extent of environmental damage due to ash, gas venting, and acid rain varies in the exclusion zone, but some areas appear qualitatively similar to sites in northern Montserrat, which are comparatively less affected by volcanic activity. Despite the availability of apparently suitable habitat, we captured only a single adult male lizard in the permanent exclusion zone, suggesting that volcanic activity in this area may have a dramatic impact on lizard abundance.

Additionally, we compared body size among populations of *A. lividus* across the island, and compared current average body size to those of ethanol-preserved specimens in the Museum of Comparative Zoology collections at Harvard University, which were collected before the major volcanic eruption. We find that average body size (snout–vent length) is lower in recently-sampled populations, which may indicate that persistent volcanic episodes periodically deplete populations, making it rare for males to attain larger body sizes. Interestingly, however, the sole male found in the exclusion zone was also the largest collected to date, suggesting that large body size may facilitate colonization or persistence in this highly disturbed area. Because lizard abundance in the exclusion zone is extremely low, it is possible that volcanic activity may cause local extinction and may also delay or hamper recolonization.

Materials and Methods.—Because of the periodic fluctuations in volcanic activity, Montserrat is subdivided into zones that vary according to risk, which the Montserrat Volcano Observatory (MVO) monitors and updates according to current conditions (Fig. 3). While most of the north is permanently open, areas south of Salem in the west and Jack Boy Hill in the east are restricted, especially when volcanic activity increases. Even when the volcano is relatively calm, these areas are more affected by acid rain, ash, and pyroclastic activity than the northern half of the island. Travel into the permanent exclusion zone is prohibited, but the MVO granted our team special permission to enter the northwestern fringe of the exclusion zone for one day (29 June 2009) to survey *Anolis*

lividus, providing a first glimpse into lizard habitat conditions in this area.

In the exclusion zone we visited six sites of varying degrees of volcanic impact and seven sites outside of the zone (Table 1, Fig. 3). Because our time was limited in the exclusion zone, we qualitatively assessed each site we visited for relative ash, sulfur, and acid rain impact as compared to sites we visited in the safe zone. Ash impact referred to abundance of standing ash. We considered a site to have low ash impact if only a light coat of ash was present, no more than a few centimeters deep, and high impact when large quantities of standing ash were present, often at least half a meter high. Two observers confirmed the odor of sulfur and the presence of trees denuded of leaves with blanched trunks and branches were considered strong evidence of acid rain damage.

We captured adult male lizards with a standard noose and using digital calipers we measured body length (snout–vent length; SVL), which is the distance from the tip of the snout to the cloaca. We captured and measured individuals from populations outside of the exclusion zone in the winters of 2009 and 2010 (N = 43) and in the summer of 2009 (N = 30). We kept summer and winter individuals separate for statistical analyses because population body size can vary by season in lizards.

We also measured SVL for 41 ethanol-preserved specimens of adult male *A. lividus* from the Museum of Comparative Zoology at Harvard University, all of which were captured before the 1995 eruption (Table 1). While there was no minimum body size for inclusion in our analyses, we only considered samples captured in summer because of low sample size for museum specimens captured in winter. Because exact coordinates are unavailable for these animals we provide approximate localities based upon the available information of capture site. We performed all analyses on log-transformed data using SPSS ver. 16.0 statistical software (SPSS Inc., Chicago, Illinois; http://www.spss.com). We conducted

FIG. 4. Image of several trees and a satellite dish damaged by acid rain in St. George's Hill (SGS), in the exclusion zone. The damaged trees are defoliated with blanched trunks and branches.

a one-way ANOVA on mean body length to determine if SVL of ethanol-preserved specimens differed from that of the animals we captured in summer and in winter. We performed post-hoc tests (Tukey) to identify populations that differed from each other.

Results.—While sites in the north are qualitatively quite similar to each other, there are pronounced environmental differences between the sites visited in the exclusion zone (Table 1). Ash impact in Fox's Bay and Weeke's was low and comparable to sites outside of the exclusion zone (Air Studios, Northeast Field, Jack Boy Hill), but the remaining sites had considerably more ash present. Acid rain damage was noticeable only in St. George's Hill, although it may affect other sites to a lesser extent (Fig. 4). We noticed a distinct sulfurous odor in the air in all exclusion zone sites except Weeke's, and it was not appreciable anywhere outside of the exclusion zone. While the sites within the exclusion zone differed from each other environmentally, they were similar in that lizard abundance was very low. While lizards were abundant in the sites sampled outside of the exclusion zone, we observed only two animals (a mating pair) in a day of surveying, both of which were perching on the same tree in Weeke's.

We divided our data into three groups: winter 2009/2010, summer 2009, and summer-collected museum specimens. Histograms (Fig. 5) show the distributions of body size for the summer 2009 (N = 30, mean = 56.9 mm, SD = 5.7), winter 2009/2010 (N = 43, mean = 53.9 mm, SD = 6.8), and museum collection lizards (N = 41, mean = 59.9 mm, SD = 5.8). The male we caught in the exclusion zone (SVL = 67.9 mm) is also the largest lizard we have sampled to date across all seasons. However, several lizards from the museum collections were larger than this male, and the largest lizard sampled on Montserrat is 70.8 mm in body length. An analysis of variance (ANOVA) revealed that mean SVL differed significantly between groups sampled ($F = 9.785$, df=2, $p < 0.001$), and a post-hoc test (Tukey) showed that only the winter samples and the museum specimens were significantly different from each other ($p < 0.001$).

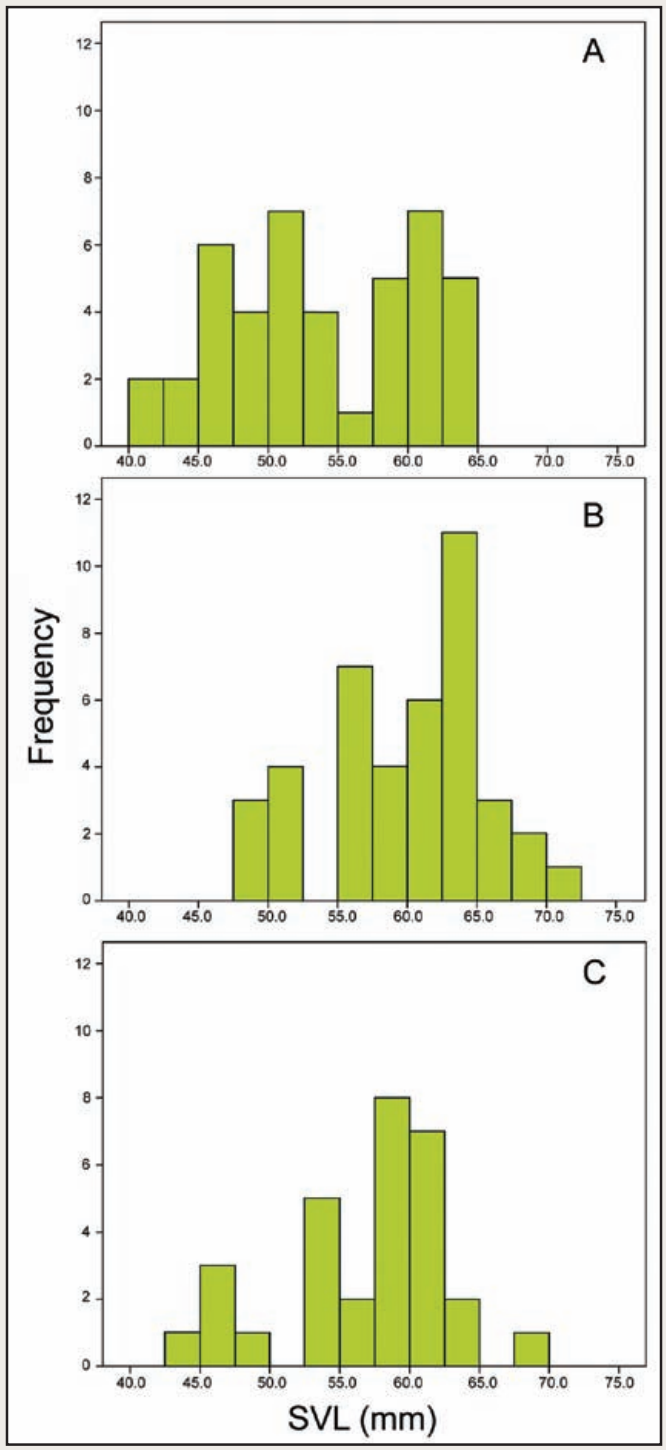

FIG. 5. Histograms depicting distributions of body length (SVL) for (a) lizards captured in winter 2009/2010, (b) museum specimens captured in summer before the eruption of 1995 (c) lizards captured in summer 2009.

Discussion.—Our field observations revealed that habitats within the exclusion zone differed qualitatively in their degree of volcanic impact. Most importantly, the sites closest

to the boundary of the exclusion zone, Fox's Bay and Weeke's, appeared very similar to our sampling sites outside the zone, except that a sulfurous odor was appreciable in Fox's Bay. Despite being qualitatively more similar to the northern portion of Montserrat, all sites within the exclusion were alike in that *Anolis lividus* was uniformly scarce. We sampled as close to Plymouth as we could safely get (Richmond Hill), where *A. lividus* was considered ubiquitous before the eruption and now appears absent or nearly so (Lazell 1972). The only two lizards that we found in the exclusion zone were a mating pair in Weeke's, the site that is physically closest to the exclusion boundary and also qualitatively most similar to the north. Furthermore, this male was the largest lizard by more than 3 mm that we have sampled to date (although it is also 3 mm smaller than the largest museum specimen).

Mean body size in winter-caught lizards was significantly smaller than the summer-caught museum population, which is not unexpected because body size increases from winter into the breeding season. However, if seasonal effects alone could account for the difference in body size between museum and winter-caught specimens, then the winter specimens should also be significantly smaller than our summer-caught specimens, but this is not the case. Although not significant, there is a trend towards larger average body size in the museum specimens than in the summer 2009 samples. This may reflect a collection bias towards larger animals in the museum collections, but cannot explain why we have not caught larger animals. The largest museum specimen (SVL = 70.8 mm) is much larger than the biggest (SVL = 67.9 mm) and second largest (SVL = 64.5 mm) specimen, collected at Weeke's and Happy Hill, respectively. Our collection technique is completely agnostic; we capture any adult males we see and given that larger males should be more conspicuous it appears that larger males are potentially less abundant..

Population size in anoles can be quite large, especially in the West Indies, and is fairly constant between years (Andrews 1979; Losos 2009; Schoener 1985, but see Schoener and Schoener 1978). The scarcity of anoles in the exclusion zone, an area where *A. lividus* once abounded, suggests that populations within the exclusion zone potentially go locally extinct more often, and that more persistent environmental assaults in that area may retard recolonization efforts as compared to sites further north. Although recolonization by canopy insect populations is quite rapid (Marske et al. 2007), it would likely take more time for lizards, which have a longer generation time and take longer to disperse than flying insects. Furthermore, dispersal from the north into more suitable parts of the exclusion zone may be hampered by the Belham River valley, a wide mudflat straddling the exclusion boundary, as this barren riverbed is periodically covered in ash and pyroclastic material. However, long-term ecological surveys are needed to tease apart the patterns affecting local abundance and extinction. As we sample populations at a single point in time we lack detailed data regarding the ecological fluctuations a given region has undergone due to volcanic activity that can affect local extinction and recolonization.

If periodic episodes deplete populations closer to the exclusion zone more often, then it would be rare for males to live long enough to grow very large in that area, but the largest male we sampled in our trip came from Weeke's, in the exclusion zone. It is possible that larger animals are more resilient to periodic environmental fluctuations, such as crashes in insect populations. Larger lizards are socially dominant over smaller males, and have better territories, which may be more important in areas that are periodically food-limited by crashes in insect populations (Rand 1967; Stamps and Krishnan 1994; Stuart-Smith et al. 2007; Trivers 1976). Again, more sampling in the permanent exclusion zone is needed to determine if the male we caught was rare, or if there is greater size spread in populations close to the volcano. Further investigation of *Anolis lividus* both within and outside the permanent exclusion zone will provide insights into the ecological processes influencing response to continual volcanic activity.

Material Examined.—All samples are from the Herpetology collections at the Museum of Comparative Zoology (MCZ) at Harvard University. Specimen numbers and corresponding localities are provided. MCZ 18318 (Plymouth), MCZ 38379 (Plymouth), MCZ 57785 (Plymouth), MCZ 57786 (Plymouth), MCZ 57787 (Plymouth), MCZ 65333 (Plymouth), MCZ 65335 (Plymouth), MCZ 82022 (Plymouth), MCZ 82023 (Plymouth), MCZ 82024 (Plymouth), MCZ 82025 (Plymouth), MCZ 82026 (Plymouth), MCZ 82027 (Plymouth), MCZ 82028 (Plymouth), MCZ 82032 (Woodlands), MCZ 82033 (Woodlands), MCZ 82034 (Woodlands), MCZ 82035 (Woodlands), MCZ 82036 (Woodlands), MCZ 82037 (Woodlands), MCZ 82038 (Woodlands), MCZ 82044 (Farm Estate), MCZ 82045 (Farm Estate), MCZ 82046 (Farm Estate), MCZ 82047 (Farm Estate), MCZ 82048 (Farm Estate), MCZ 82049 (Farm Estate), MCZ 82050 (Farm Estate). Collected by Julian Boos in 1970: MCZ 125465 (Salem), MCZ 125466 (Salem), MCZ 125468 (Monkey Hill River), MCZ 125469 (Monkey Hill River), MCZ 125470 (Emerald Isle Hotel), MCZ 125472 (Emerald Isle Hotel), MCZ 125473 (Emerald Isle Hotel), MCZ 125474 (Emerald Isle Hotel), MCZ 125475 (Emerald Isle Hotel), MCZ 65331 (South Soufrière), MCZ 82042 (Mount Chance), MCZ 82043 (Mount Chance), MCZ 55837 (Unknown).

Acknowledgments.—Our research was supported by National Science Foundation grants to J. H. (DEB-0816515) and our collaborator, Bruce Jackson (award number DEB-0511791). We thank R. Stewart and the Montserrat Volcano Observatory for granting permission to visit the permanent exclusion zone, R. Malin for allowing us to join his surveying team, and G. A. L. Gray and the Montserrat Department of Agriculture for expediting our requests to conduct research on *Anolis lividus*. We acknowledge the work of our field assistants and local contacts, D. Campbell, T. Campbell, J. Fergus, D. Harenda, S. Mosher, K. Parker-Johnson, E. Snyder, and S. Stuck. We thank J. Lazell, J. Boos, A. Algar, B. A. S. Bhullar, Y. Stuart, D. L. Mahler, and

J. Losos for helpful comments during the preparation of this manuscript.

Slevin's Bunchgrass Lizard (*Sceloporus slevini*) Population Barely Extant on the Sonoita Plain, Arizona

Species can be rare because they are truly rare, highly spatially clumped, or elusive due to species characteristics, and when all three determinants are operating there is a compounded effect on rarity (McDonald 2004; Rabinowitz 1981). For species that are truly rare it is important to obtain reliable information on population trends and to determine whether downward trends are simply natural population fluctuations or trajectories likely to result in extinctions (Barrows 2006). Ultimately, however, the critical need is to determine the reasons for rarity so that appropriate conservation measures can be implemented (Barrows 2006; Roberts et al. 2009). Slevin's Bunchgrass Lizard, *Sceloporus slevini* (formerly *S. scalaris slevini*, see Smith et al. 1996) meets all three of the above determinants of rarity within its limited range in the United States. This small and secretive species is a bunch grass specialist that is rarely observed far from its bunch grass refugia (Fig. 1). Although widely distributed at high elevations along both axes of the Sierra Madre Occidental of Mexico from northern Durango to northern Chihuahua, in the United States it occurs in a limited series of disjunct populations, largely within the Madrean Archipelago of southeastern Arizona where populations are mainly confined to isolated montane meadows above 2100 m (Smith et al. 1997). In addition, several disjunct lower elevation populations (~1300–1600 m) have been recorded in the plains grasslands of Arizona and New Mexico (Bock et al. 1990; Dixon and Medica 1965; Lowe 1964; Smith et al. 1998; Stebbins 2003).

Anthropogenic and non-anthropogenic events have been implicated in the reports of past and recent population declines of *S. slevini* at sites where they were once abundant. Ballinger and Congdon (1996) searched the study areas they worked in the Chiricahua Mountains in the 1970's when densities ranged from 100–200 lizards per hectare (Ballinger and Congdon 1981), but found only four juveniles, attributing the decline to overgrazing by cattle. In 1998 *S. slevini* was reported "decimated" at the National Audubon Society Appleton-Whittell Research Ranch (ARR), a relatively low elevation site (~1478 m) on the Sonoita Plain of Arizona (Smith et al. 1998). Despite intensive searching during June–September of 1997, a group of researchers failed to find any *S. slevini* (Smith et al. 1998). Nine years previously, relatively high numbers of lizards had been recorded at the same sites (Smith et al. 1998). For example, from 12–20 August 1989, 53 adults were recorded from ARR and adjacent areas of the Sonoita Plain (Bock et al. 1990). One of us (TM) also worked at ARR during the mid-1990's when lizards were abundant (Mathies and Andrews 1995) and similarly noted their subsequent disappearance. The decline and potential extirpation of this population was attributed to a prolonged drought (Smith et a1. 1998).

The population of *S. slevini* at ARR is considered important, in part, because it is one of the few large populations known in plains grassland (Bock et. al. 1990). There are also differences in life history attributes between the ARR population and montane populations, including the phenology of reproduction, two vs. one clutch of eggs a season (Mathies and Andrews 1995), and a larger body size (Mathies and Andrews 1995; C. d'Orgeix, unpubl. data). Genetic differences are implied by the absence of unicolor individuals in the ARR population (Smith et al. 1990; T. Mathies, unpubl. data). Unicolor individuals occur in various proportions in the montane populations in northern Chihuahua, Mexico (22%; Anderson 1972) and the United States (20%; Van Devender and Lowe 1977). Unicolor individuals also occur in populations in close proximity to the ARR population in the Huachuca Mountains at Ramsey Canyon (Smith 1946), and on Carr Peak (C. d'Orgeix and T. Mathies, unpubl. data), indicating a lack of genetic exchange between ARR and montane populations. Because of the possible differentiation of this population from other nearby populations, our objectives were to determine whether the species is still extant at ARR, and if so, to establish survey plots and methodology for future monitoring efforts.

Materials and Methods.—Our study area is on the 3160-ha ARR on the Sonoita Plain, Santa Cruz County, Arizona, a plains grassland-oak savanna, which unlike the surrounding region, has not been grazed by livestock for over 42 years. Stratified sampling was used to select 10 sites in areas that appeared to be good habitat for *S. slevini*, having primary coverage of bunch grasses interspersed with low woody shrubs and patches of bare soil. One 100 x 100 m plot was established on each site by selecting a random position as plot corner and then mapping out the other three corners in Universal Transverse Mercator coordinates (Datum: NAD27 CONUS) using handheld global positioning system (GPS) units (Models: GPSmap 60CS and Rhino530, Garmin International Inc., Olathe, KS, USA). Three of the 10 sites were located within the area where Bock et al. (1990) initially found *S. slevini* to be abundant (C. Bock, pers. comm.), and where Smith et al. (1998) later found them apparently absent. Plots

were surveyed 10 June to 29 July, 2007 [10 years after Smith et al. (1998)] and again 24 July to 4 August, 2009. Each plot was surveyed three times each year on three different days. A GPS unit was used to navigate a series of parallel non-overlapping "transects" across the width of each plot. Each transect was surveyed by two to three persons walking side by side approximately two meters apart. Plots were surveyed between 0730 h and 1800 h when conditions were sunny, or if overcast, when air temperatures were high enough for lizard activity (see Mathies and Andrews 1995). We walked 8 to 11 transects per plot per day at about 2.5 kph with each person walking a total of about 1080 m distance per plot. Lizards were located visually while walking transects and captured by hand. To identify individuals we recorded their sex and measured each lizard's snout–vent length (SVL) to the nearest 1 mm, body mass to nearest .01 g and removed 2–4 mm of tissue from the tip of the tail. GPS location was recorded and the lizard was released at its point of capture. Individuals were subsequently identified based on the missing tail tip, location, sex, SVL, and mass. Coordinates of plot corners and individual *S. slevini* were mapped using ArcView (Version 3.2, ESRI, Redlands, CA, USA) Geographical Information System (Fig. 2).

Results and Discussion.—We confirmed that *S. slevini* was present at ARR on both years of the study. However, despite intensive searching, few were encountered in 2007 (N = 5, 2 males and 3 females) and in 2009 (N = 3, 2 females and 1 male). Thus, densities appear to be quite low (1–2.5 lizards per 100 m^2, for occupied plots). Lizards were detected on four of our ten plots. The only plot on which lizards were detected in both study years was Plot 2, which was within the area censused by Smith et al. (1998). Four of the five lizards detected in 2007 were on Plot 5, but we detected no lizards there in 2009. Within years, only one of the eight lizards found was recorded on a subsequent census. These data contrast with 2006 and 2007 censuses of a high elevation population in the Huachuca Mountains where the same individuals were seen on subsequent days at the same locations (D. Bridgers, C. d'Orgeix, and T. Mathies, pers. obs.).

In 1989 when lizard densities were high, Bock et al. (1990) encountered approximately 9 lizards per man-hour. However, in 1997 Smith et al. (1998) walked a total of 7 km in June and again in August reporting a total absence of *S. slevini*. We found that detection of a single *S. slevini* on our plots in 2007 and 2009 required coverage of about 6.4 km and 10.7 km of transect at about 2.5 and 4.3 man-hours, respectively.

Smith et al. (1998) suggested that *S. slevini* is adapted to the more mesic high elevations and that the two consecutive years of severe drought (1995–1996) preceding the observed decrease was the cause of the ARR population decline. Precipitation data from ARR support both contentions; prior to the observed abundance in 1989, the study area experienced two consecutive years of much higher than average precipitation (1983, 1984) followed by another four consecutive years of above average precipitation (Fig. 3A). Except 2000,

FIG. 1. Male *Sceloporus slevini* in the bunchgrasses *Bouteloua gracilis* and *B. curtipendula* at the National Audubon Society Appleton-Whittell Research Ranch, Santa Cruz County, Arizona.

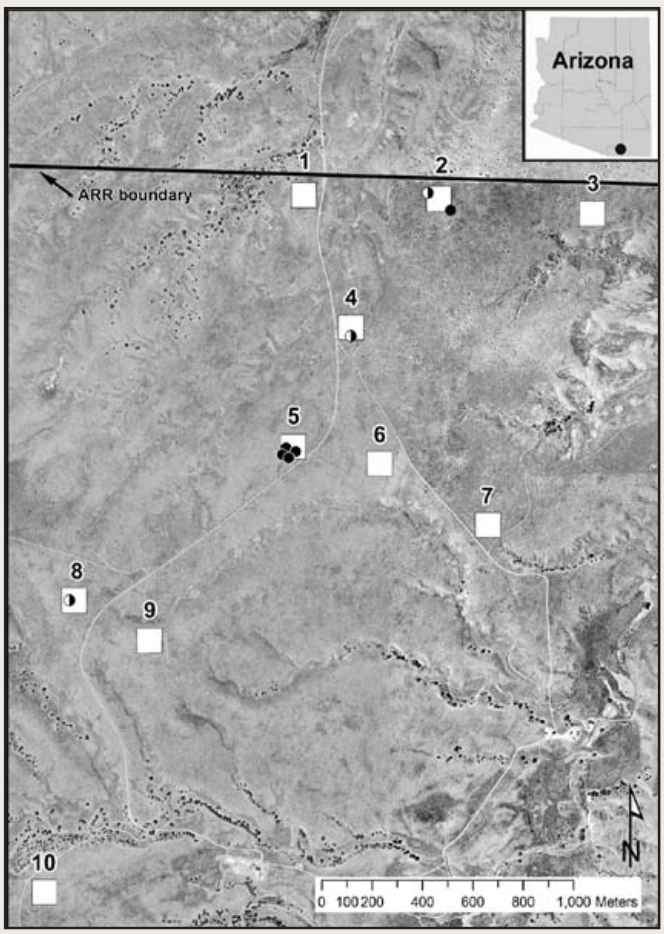

FIG. 2. Distribution of the ten 100 x 100 m survey plots for bunch grass lizards, *Sceloporus slevini,* on the National Audubon Society Appleton-Whittell Research Ranch (ARR), Santa Cruz County, Arizona. The filled circle in the inset indicates the general location of the study area. Numbers above plots are plot numbers. Filled (2007) and half-filled (2009) circles are the locations of the eight *S. slevini* detected in this study.

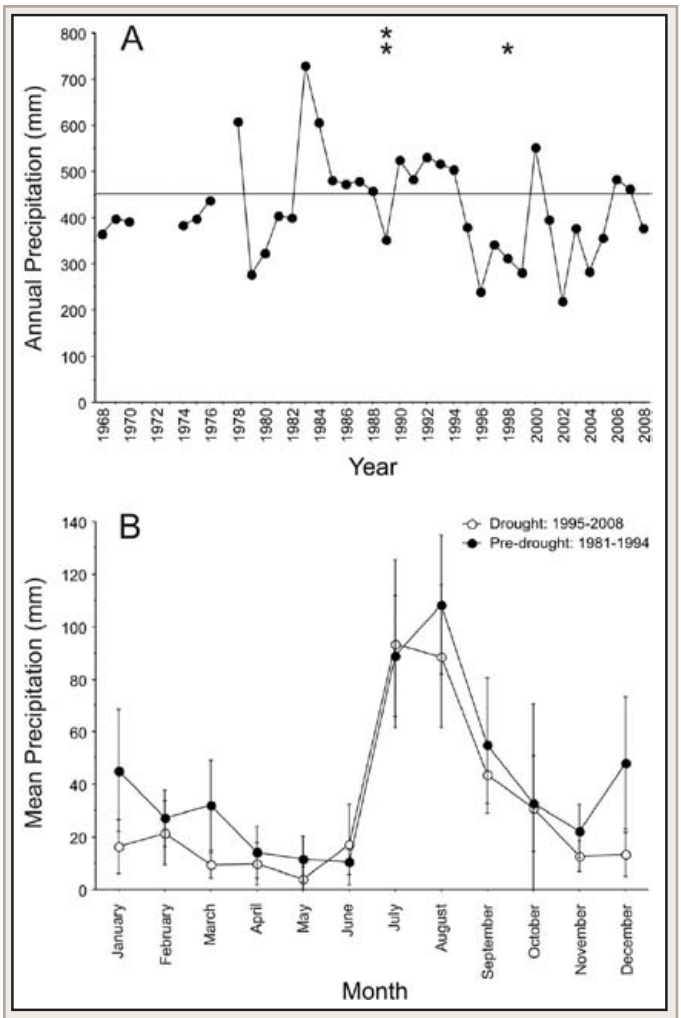

FIG. 3. A) Annual precipitation at the National Audubon Society Appleton-Whittell Research Ranch, Santa Cruz County, Arizona. Data for years 1971–1973 and 1977 were not available. The horizontal line represents the mean precipitation for 23 years of available data from 1968–1994 prior to onset of drought in 1995. Double asterisks indicate year when high densities of *Sceloporus slevini* were observed (1989: Bock et al. 1990); single asterisk indicates year when no lizards were observed (1998: Smith et al. 1998). B) Mean (± 95% confidence interval) precipitation by month. Filled circles are for 14-year period prior to onset of drought (1981–1994); unfilled circles are for 14-year period from when recent drought began (1995) to present (2008).

2006, and 2007, below average precipitation totals have continued to present (Fig. 3A).

Certain life history attributes of *S. slevini* enable rapid population increase under favorable environmental conditions. Unlike females in nearby montane populations, females in the ARR population can produce two clutches a season (Mathies and Andrews 1995; see also Ortega and Barbault 1986). Moreover, *S. slevini* is an early maturing species; because hatchlings are periodically active on sunny winter days and exhibit winter growth, sexual maturity is attained by the first spring (Ballinger and Congdon 1980; Newlin 1976). However, other attributes would result in rapid population decline if this species is sensitive to drought. Adults are short-lived with an estimated yearly mortality of 62-76% in a montane population (Ballinger and Congdon 1981). Thus any population sustaining two consecutive years of no recruitment could be reduced to low levels or extirpated.

Precipitation data for the months when nesting and egg incubation occur do not support the idea that drought directly affected egg laying and hatching success. Again, when comparing the 14-year period of pre-drought years and the subsequent 14-year period of drought years, mean monthly precipitation for the three months when egg laying and hatching occur (July–September: Mathies and Andrews 1995) did not differ (two-factor ANOVA; $F_{1,75} = 1.16$, $P = 0.28$), nor was the interaction significant (Fig. 3B; $F_{2,75} = 0.99$, $P = 0.38$). The drought has instead been primarily manifest in the months outside the July–September nesting-hatching season (two-factor ANOVA; $F_{1,224} = 12.19$, $P = 0.0006$). Because *S. slevini* is an early maturing species with rapid population turnover, population persistence requires that hatchlings of both sexes grow substantially during these months in order to reach sexual maturity by first spring. Maturing females, in addition to obtaining resources necessary for growth, must also acquire food for the fat body growth required for egg production. Food abundance and growth rates of all size classes of *S. slevini* were shown to be lower in a drought year than a non-drought year (Ballinger and Congdon 1980) and the phenology of fat body development in females indicates that reserves accumulated in the fall are used for egg production in the spring (Newlin 1976). Regardless, a proximate mechanism for a drought-induced population crash remains unclear.

Climate change (warming) has recently been implicated in local extinctions at 12% of 200 sites surveyed since 1975 for 48 *Sceloporus* species in Mexico, and lizard extinctions are projected to increase globally (Sinervo et al. 2010). The population crash of *S. slevini* at ARR may therefore be symptomatic of this larger trend. However, another low-elevation Sonoita Plain population, approximately 30 km SW of ARR, appears to have relatively high numbers of lizards (C. d'Orgeix and T. Mathies, pers. obs.), and high elevation populations in the Huachuca and Chiricahua Mtns. appear to be robust (C. d'Orgeix and T. Mathies, pers. obs.). These data contrast with the expectation that either other nearby low elevation populations should show similar declines in population numbers, or that lower elevation populations should be less adversely affected by global warming than higher elevation populations (Sinervo et al. 2010). Furthermore, the contrasts in population numbers between ARR and other nearby populations indicate that environmental complexity (Barrows and Allen 2007) masks the proximate causes for the decline at ARR.

Our primary finding that the population at ARR remains extant, albeit at extremely low numbers, presents a unique opportunity to compare this population's dynamics with those of other populations of *S. slevini* at both low and high elevations to test hypotheses of drought influenced

population declines (Barrows 2006), differences in environmental complexity between populations (Barrows and Allen 2007) and climate change extinctions (Sinervo et al. 2010).

Acknowledgments.—We thank two anonymous reviewers for comments and suggestions. Research was conducted under Arizona Game and Fish Department scientific collecting permits to Christian d'Orgeix. All applicable institutional animal care guidelines were followed. Field assistance was provided by Tierra Alvin, Sarecia Harris, and Jonathan Jeffreys. Funding was provided to Tierra Alvin, N. Danielle Bridgers, and Sarecia Harris by the Louis Stokes Alliance for Minority Participation, and to N. Danielle Bridgers under an Ariel Appleton Research Fellowship. Linda Kennedy at the National Audubon Society Appleton-Whittell Research Ranch provided logistic support. Precipitation records and valuable discussion were provided by Carl Bock and Chris Hall.

Using Scrape Fishing to Document Terrapins in Hibernacula in Chesapeake Bay

Chesapeake Bay's Diamondback Terrapin (*Malaclemys terrapin terrapin*) population has made considerable recovery from the commercial exploitation that led to its near extirpation in the late 19th and early 20th centuries (Carr 1952; McCauley 1945). Nevertheless, it continues to face increasing threats from human population growth, degradation of the Bay, exposure to man-made hazards (Butler et al. 2006; Roosenburg 1991; Siegel and Gibbons 1995), and, during the period of this study (2003–2005), continued commercial harvest in the Maryland portion of the Bay. The state of Maryland maintained an active terrapin fishery that was closed only during the terrapin nesting season (May–July), had no daily or seasonal catch limit, and exclusively targeted breeding-age females, i.e., terrapins with plastron length ≥15.2 cm. Although the fishery was perceived as small, with little market demand, the long season and 'no limit' regulation left the fishery vulnerable to overharvest. Concern over this vulnerability led us to examine the method of traditional winter harvest and characteristics of terrapins occupying hibernacula. Although generations of Chesapeake Bay watermen have pursued winter harvest of terrapins, fishing methods, locations of hibernacula, and the terrapins occupying them have not previously been documented.

Here we utilize watermen fishing skills and harvest methods to locate, sample, and describe terrapins occupying estuarine bay hibernacula. Because the region has long been a center for the commercial harvest of Blue Crabs (*Callinectes sapidus*), we also examine terrapin captures for potential effects of selective by-catch mortality of small terrapins associated with decades of commercial crab pot use in the region (Roosenburg et al. 1997; Warner 1977; Wood 1997).

MATERIALS AND METHODS

We sought collaboration with a former terrapin harvester to learn fishing methods and to access hibernacula in the Tangier Sound region of Chesapeake Bay (Fig. 1). Tangier Sound is bordered by extensive brackish tidal marshes and historically has harbored large terrapin populations (McCauley 1945). Sampled hibernacula were chosen to be geographically separated and to represent a selection of sites of former terrapin harvest. Four sites were chosen near large marsh islands ca. 8–12 km offshore (Smith Island, South Marsh Island, and Bloodsworth Island) and two additional sites were located near the mainland (Janes Island and Nanticoke River; Fig. 1). Two sites located within tributaries (Nanticoke River and Janes Island) and a third located within interior South Marsh Island were within zones where commercial crab potting is prohibited by state regulation. The remaining three sites (Smith Island–N, Smith Island–S, and Bloodsworth Island) were within areas of heavy potting activity. We also selected St. Jerome Creek, a site of former harvest on the western shore of Chesapeake Bay that differed in being located in a navigable tidal creek having forested shoreline in lieu of extensive bordering salt marsh.

To capture terrapins watermen adapted a dredge, or scrape, used to capture molting blue crabs from shallow, near-shore waters using locally built, shallow-draft vessels (also called scrapes; Warner 1977). Being hand-made, terrapin scrapes vary in size, but most are based on a 1.5 m wide blue-crab design. In 2003, we used a blue crab scrape that was modified by attaching a larger mesh catch bag and welding 12 short 7.6 cm teeth every 13 cm along the scraping bar. The larger mesh bag (8 cm) helped minimize fouling and the teeth dug terrapins from bottom sediment. In 2004 and 2005, we used a slightly larger scrape framed from heavier 2 cm diameter steel stock. Its entrance measured 1.7 m × 0.4 m and its overall length was 2.4 m (Fig. 2a). The noteworthy difference of this scrape was the addition of numerous (30), longer (15 cm), and more closely spaced (6 cm) teeth on the scrape bar.

The scrapes were towed in a circular pattern behind a 12 m work boat and retrieved by hydraulic winch. The length of the tow rope was critical to proper operation as it adjusted the drag or "bite" of the scrape in bottom sediment. Capture success was measured by the number of terrapins captured/tow. Although there was no fixed time limit for each tow, several hundred tows averaged about 7 min in length, or a rate of 8.6 tows/h. While some commercial scrapes were equipped with side baffles to help guide terrapins into the catch bag, neither of our scrapes had baffles.

Captured terrapins were given a visible mark by drilling a 5 mm diameter hole in the 10th right marginal scute through which we attached a serially numbered monel fish tag (tag no.1005–3: National Band and Tag Co., P.O. Box 72430, Newport, Kentucky 41072). Passive integrated transponders, or PIT tags (model TX1400L: Biomark, Inc., 7615 West Riverside Drive, Boise, Idaho 83714), were used as permanent marks. Size dimorphism and tail characteristics (tail length and anus position in relation to edge of carapace) were the primary

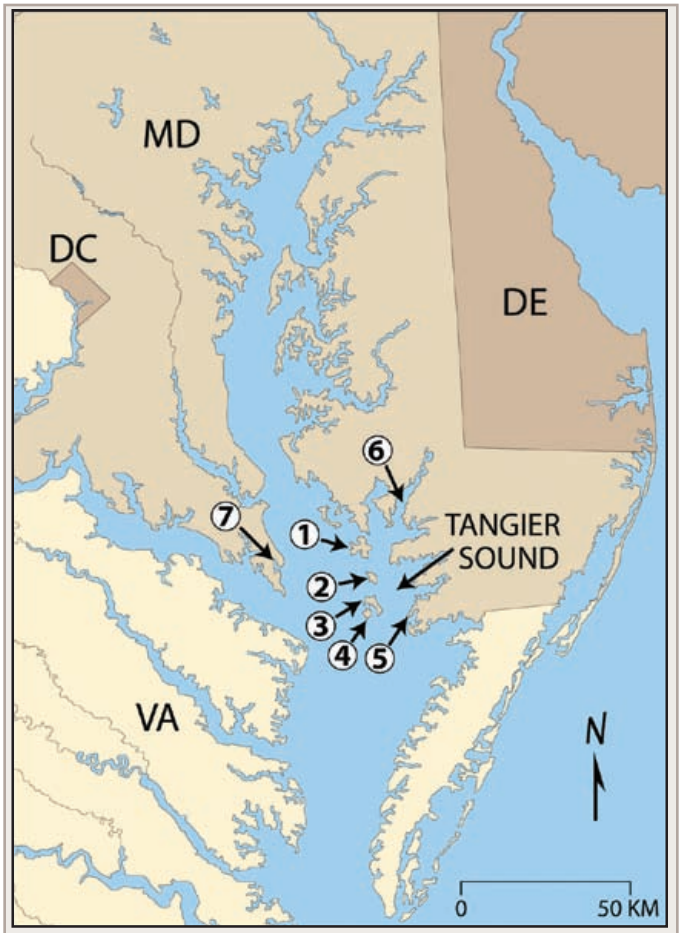

FIG. 1. Chesapeake Bay and vicinity showing Tangier Sound and the location of sites of winter sampling of Diamondback Terrapins, 2003–2005: 1) Bloodsworth Island, 2) South Marsh Island, 3) Smith Island–North, 4) Smith Island–South, 5) Janes Island, 6) Nanticoke River, and 7) St. Jerome Creek.

criteria used to sex terrapins (Carr 1952). Because only terrapins about 10 years of age (YOA) or younger could be aged by annular growth rings (as read from plastral pectoral scutes), we separated captures into two basic age classes: those ≤10 and those >10 YOA. Body mass was measured with a digital electronic balance to the nearest g and midline plastron length (PL) was measured with calipers to the nearest mm.

To dispel concerns about possible detrimental physiological effects associated from removal of terrapins from hibernacula, we conducted a field study to determine if short-term acute effects did occur. This question has management relevance because we observed commercial terrapin harvesters leaving captures on boat decks for up to several hours before sorting their catch and returning culls to the bay. In our experiment, one set of 12 newly captured terrapins (6 of each sex) were maintained in bay water (5°C) while simultaneously exposing a second set of 12 terrapins in a heated boat cabin at ca. 24°C, a temperature well above the range of ambient air temperatures (10–15°C) experienced on a boat deck on a mild winter day. Both sets of terrapins were held for a

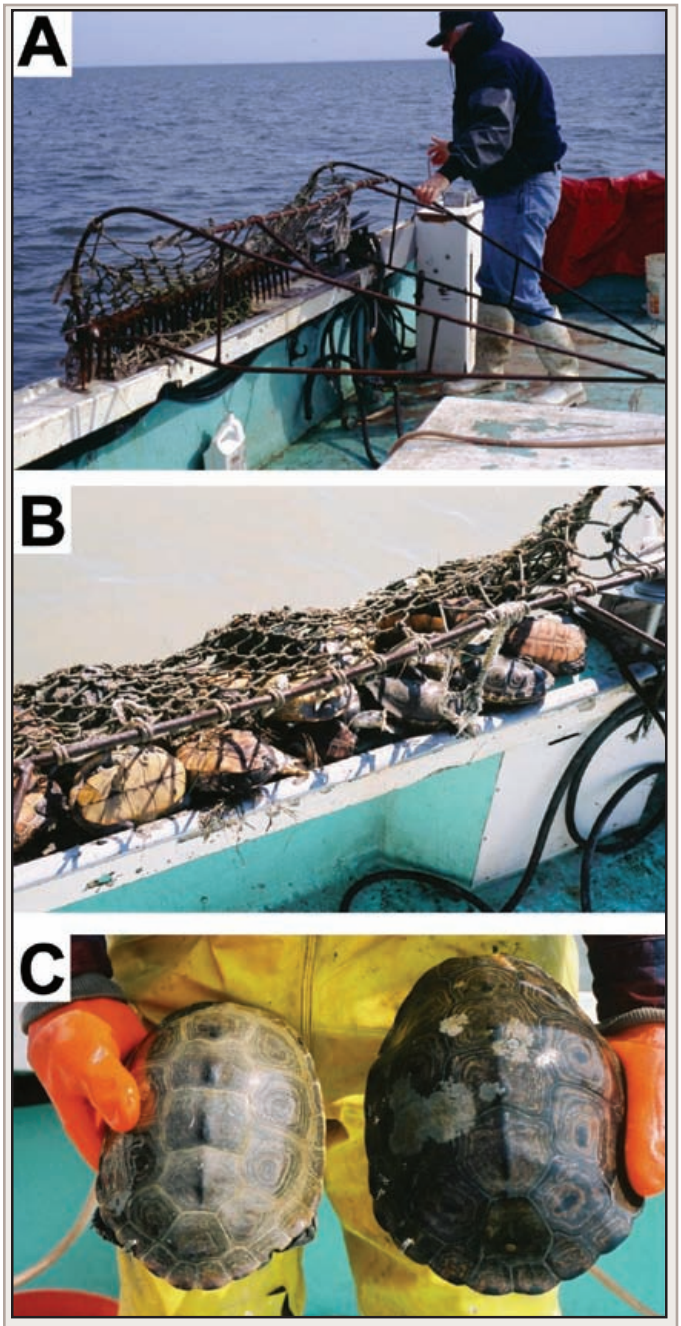

FIG. 2. A) A scrape, or dredge, used to harvest Diamondback Terrapins in winter in Chesapeake Bay. Design is based on a scrape used to harvest blue crabs but with heavier construction, addition of teeth on the scrape bar, and a larger mesh catch bag (see text for details). B) A retrieved scrape resting on the boat gunwale showing a good catch of terrapins. The scrape did not injure terrapins and as many as 24 were captured in a single tow. C) Two females caught 18 March 2005 from St. Jerome Creek demonstrate size and age in the diamondback terrapin. The female on the left (body mass of 1922 g, PL of 202 mm) was known to be 20 years of age by previous marking on the nearby Patuxent River (W. Roosenburg, pers. comm.). The female on the right is of unknown age and was the largest terrapin caught during our study (3022 g, PL of 228 mm). This specimen approximates the maximum size for the species within the Chesapeake Bay and likely within the species' range.

TABLE 1. Numbers and sex ratios of Diamondback Terrapins captured from six hibernacula in Tangier Sound and the St. Jerome Creek Site on the western shore of Chesapeake Bay, winters 2003–2005. Sites are listed by rank in cumulative sex ratio given as proportion female (*pf*).

Site	No. captures	Sex ratio (*pf*)
St. Jerome Creek	33	0.970 A[a]
Smith Island–S	74	0.784 B
Janes Island	222	0.734 B
Smith Island–N	377	0.719 B
South Marsh Island	141	0.709 B
Bloodsworth Island	160	0.588 C
Nanticoke River	168	0.345 D
Totals	1175[b]	0.660

[a] Values sharing the same letter are not different: individual 2-tailed z-tests of proportions ($\alpha = 0.05$).
[b] Totals exclude between-year recaptures (N = 22).

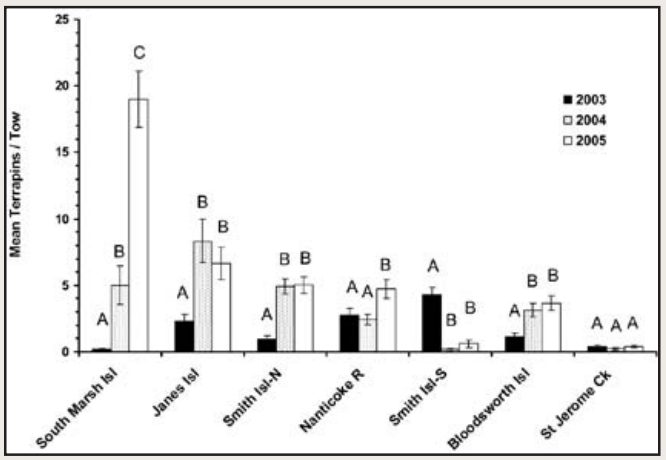

FIG. 3. A composite histogram of year- and site-specific terrapin capture rates (mean ± SE captures/tow) using a modified crab scrape in 2003 and a slightly larger scrape in winters 2004–2005. Capture rate had marked year and site effects ($P < 0.001$, individual tests using Kruskal-Wallis one-way ANOVA on ranks). Means within sites sharing the same letter do not differ: Dunn's multiple comparison test ($\alpha = 0.05$).

period of 2 h. Following the holding period, all terrapins were returned to the location of capture and placed in a 1.8 m × 2.4 m × 1.8 m wire holding cage made of 2.5 cm mesh galvanized chicken wire. The cage sat on the bottom and extended above tide level. After 3 weeks, the cage was retrieved and survival and outward condition of the terrapins assessed.

We used SigmaStat 3.1 (Systat Software, Inc, Point Richmond, California 94804) to evaluate assumptions of normality and homogeneous variance and to conduct analyses of variance. When necessary, we either transformed data to meet normality and equal variance or applied the nonparametric Kruskal-Wallis ANOVA test on ranks. Contrasts were tested using Tukey's test (parametric) or Dunn's method (non-parametric). Sex ratios and proportion of females <10 YOA were tested by 2-tailed *z*-tests of binomial proportions (Sokal and Rohlf 1995). We generated a simple Lincoln-Petersen estimate based on site-specific between-year recaptures to estimate hibernaculum population size (Seber 1973). This estimate is made under the assumption of population closure and equal catchability. We tested for two potential effects of selective by-catch mortality of smaller terrapins in crab pots as noted by Dorcas et al. (2007) and Wolak et al. (2010): larger size of both sexes based on PL and reduced presence of younger female terrapins. Data were combined across years within pot and no pot sample sites.

RESULTS

Hibernacula.—Hibernacula were located in semi-protected estuarine bays in near-shore shoal waters adjacent to extensive salt marsh. Sites had bottoms of moderately soft mud and were deep enough (1.5–3.5 m) to offer little risk of dewatering even under unusually low storm tides. Most bottoms were relatively clean of shell and organic debris; all were exposed to good tidal circulation but limited wave energy because of reduced wind fetch. Because terrapins were often buried in soft mud, continued scraping at such sites often increased capture success. On firm bottoms terrapins were only partially buried or not at all. Terrapins were not injured by capture and only rarely were they marked by the metal teeth or frame of the scrape (Fig. 2b).

Capture success.—During February and early March, 2003–2005, we captured 1175 terrapins from seven hibernacula (Table 1). Capture rate had a marked site and year effect ($P < 0.001$: individual tests, Kruskal-Wallis one-way ANOVA on ranks; Fig. 3). Capture rate for sites in Tangier Sound averaged 4.18 ± 1.02 SE captures/tow (N = 18), or about 36 terrapins/h. Capture rate generally increased in 2004 and 2005 with the use of the heavier scrape with longer, more closely spaced teeth (Fig. 3). The exceptions were the Smith Island–S site where harvest activity was suspected to have depleted the population in 2004 and 2005, and the St. Jerome site where capture success was low in all years (mean = 3.1 terrapins/h). St. Jerome Creek was the deepest site sampled at 3.5 m and during three winters produced the fewest (32 females and one male), but on average the largest terrapins. The largest, a 3022 g female with PL of 238 mm, was considerably larger than a known-age 20-year-old terrapin captured at the same site (Fig. 2c) and marked previously on the Patuxent River (W. Roosenburg, Ohio University, pers. comm.). Mass of 26 females averaged 2151 ± 56 g and PL ranged from 191 to 228 mm (mean 205 ± 1.6 mm). At our South Marsh site, heavy growth of eelgrass (*Zostera marina*) precluded capture of terrapins in 2003. However, in the absence of vegetation in 2004, capture success increased sharply, and in 2005, the site was our most productive hibernaculum, averaging19 terrapins/tow, or 160 terrapins/h (Fig. 3).

Sex ratio.—Sex ratio across all sites and years favored females: 0.66 proportion female (*pf*), or 1.94 females/male (N = 1175; Table 1). Cumulative yearly sex ratio declined from 0.730

pf in 2003 to 0.654 in 2004 and 0.641 *pf* in 2005 (P < 0.05: individual 2003 vs 2004, and 2003 vs 2005 *z*-tests of proportions). Discounting possible year effects, the decline in sex ratio was likely a result of use of the larger scrape with more numerous and closely spaced teeth that increased capture efficiency of males. Not only were generally more males captured, but the minimum size was lowered in some cases by as much as 15 mm. For sites within Tangier Sound, year- and site-specific sex ratio varied from a low of 0.32 *pf* to a high of 0.91 *pf*. The Nanticoke River, a site of known frequent terrapin harvest, was the only site where male captures outnumbered females (Table 1).

Estimate of female recruitment.—Using growth annuli to age terrapins, we found females ≤10 YOA to comprise 19.2% (145) of 764 captures. Site- and year-specific percentages varied from 0 to 39%. We estimated annual recruitment by assuming 100% annual survival in the 6-to-9 YOA classes and averaging the percent of these year classes to total annual female captures. Terrapins <6 YOA were not included because only 9 were captured (8 five-year-olds and 1 four-year-old); and 10-year-olds were excluded because advanced shell wear obscured growth annuli limiting the number that could be identified (N = 8). The 128 terrapins in the 6-to-9 year-old age classes represented 10.4%, 18.3% and 21.6 % of female captures during the respective three winters and yielded estimates of annual recruitment of 2.6%, 4.6%, and 5.4% (mean = 4.2 ± 0.83).

To eliminate potential error associated with reading growth annuli, we additionally estimated recruitment based solely on size metrics. We used mean size statistics from 44 known 9-year-old females, i.e., mean mass (1043 g), PL (165 mm), and mass-to-plastron ratio (6.340 g/mm), to separate females ≤9 YOA from all older females. The resulting mean estimates of percent annual recruitment were about 50% higher than those based on growth annuli: 6.0 ± 0.29% based on PL, 6.5 ± 0.35% based on mass, and 6.7 ± 0.16% based on mass-to-PL ratio. Although we recorded 19.2% of females ≤10 YOA, only 29 3-to-8-year-old males (7.9% of male captures) were so captured (χ^2 = 22.8, P < 0.001, 1 df). We concluded that too few males in the younger age classes were captured to provide a meaningful estimate of recruitment.

Growth rate.—Females in the 5-to-10-year-old age classes exhibited marked growth as mean mass increased by a factor of 3 (from 397 to 1184 g) and mean PL increased 50% (from 115.9 to 174.0 mm; Fig. 4). Based on the Maryland harvest regulation of a minimum PL of 152 mm, most female terrapins would reach harvestable size at between 7 and 8 YOA. Too few males were captured to adequately interpret growth in the 5-to-9-year-old age classes.

Recaptures.—We recaptured 102 terrapins (8.7% of captures) by various means up to four years after initial capture, but only 22 terrapins, 21 females (2.6% of female captures), and a single male (0.25% of male captures) were recaptured during winter sampling. All 22 recaptures were recorded at the site of original capture. Recaptures were sufficient to estimate hibernaculum population size only at the Smith Island–N site, where sampling was increased as part of an ongoing population study. Based on 13 female recaptures in 2005,

TABLE 2. Mean mass of male and female terrapins captured at six sites within Tangier Sound and St. Jerome Creek on the western shore of Chesapeake Bay, winters 2003–2005. Includes only unique adult captures (excludes between-year recaptures) of females >10 years of age and males >9 years of age. For the six Tangier Sound sites there was no rank correlation between site-specific mean mass of males and females (r = 0.54, P > 0.05, 4 df).

	Mean mass (g) ± SE			
Site	N	Female	N	Male
St. Jerome Creek	26	2150.6 ± 56.4 A[a]	—	—[b]
Smith Island–S	49	1589.2 ± 34.1 B	16	455.2 ± 5.03 A[c]
Smith Island–N	236	1386.7 ± 17.3 C	104	407.3 ± 5.03 C
Bloodsworth Island	81	1324.8 ± 34.5 CD	63	436.5 ± 7.91 AB
South Marsh Island	72	1285.8 ± 34.0 CD	32	390.9 ± 13.03 CD
Janes Island	111	1248.1 ± 23.2 D	53	358.3 ± 7.14 D
Nanticoke River	46	1181.7 ± 30.9 D	101	412.3 ± 5.39 BC
Combined	621	1393.5 ± 22.6	369	407.3 ± 3.19

[a] One-way ANOVA found marked site effect for female mass ($F_{6,614}$ = 52.2, P < 0.001). Means within columns sharing the same letter do not differ: Tukey's test (α = 0.05).

[b] Insufficient sample size.

[c] One-way ANOVA on ln transformed data found a marked site effect for male mass ($F_{5,363}$ = 16.0, P < 0.001). Means within columns sharing the same letter do not differ: Tukey's test (α = 0.05).

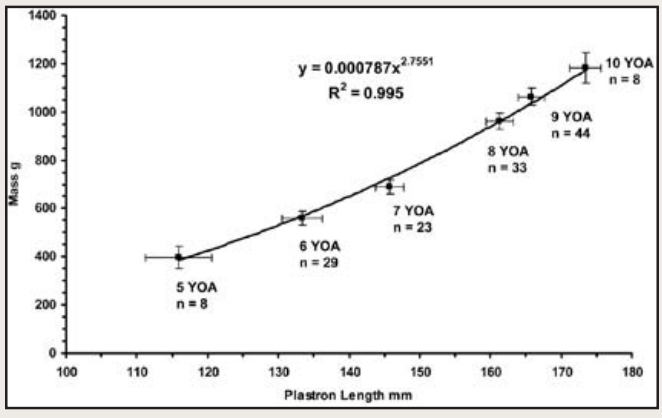

FIG. 4. Growth curve for 5- to 10-year-old female terrapins captured during winter sampling in the Tangier Sound region of Chesapeake Bay. Age was determined by counting growth annuli on plastral pectoral scutes. Points are means; brackets are ± SE. Small sample size in 5-year-olds resulted from general absence of these and younger (smaller) terrapins in estuarine bays in winter. Small sample size of 10-year-old terrapins resulted from shell wear that obscured growth annuli and limited the number that could be identified.

TABLE 3. Mean plastron length (PL) for male and female terrapins and the proportion of young females (*pf*) ≤10 years of age (YOA) captured at six sites within Tangier Sound, winter 2003–2005. Ranking in relation to zones with and without crab potting is shown. PL means include only unique captures (excludes between-year recaptures) of females >10 YOA and males >9 YOA.

Crab potting zone	Site	Mean plastron length (mm) ± SE Male (N)	Rank	Female (N)	Rank	*pf* ≤10 YOA	Rank
Pots	Smith Island–S	120.9 ± 1.16 A[a] (16)	1	186.8 ± 1.33 A[b] (49)	1	0.157 AB[c]	4
Pots	Bloodsworth Island	118.3 ± 0.73 A (63)	2	176.3 ± 1.49 BC (81)	3	0.133 B	6
Pots	Smith Island–N	116.2 ± 0.59 AB (104)	3	179.2 ± 0.72 B (236)	2	0.135 B	5
No pots	Nanticoke River	115.2 ± 0.57 B (101)	4	167.8 ± 1.40 D (46)	6	0.300 A	2
No pots	South Marsh Island	113.7 ± 1.24 BC (32)	5	174.5 ± 1.43 C (72)	4	0.309 A	1
No pots	Janes Island	111.5 ± 0.84 C (53)	6	173.9 ± 0.98 C (111)	5	0.186 AB	3
Combined		115.6 ± 0.33 (369)		178.2 ± 0.53 (595)		0.192 (764)	

[a] Kruskal-Wallis one-way ANOVA test on ranks found a marked site effect for plastron length (H = 48.0, P < 0.001, 5 df). Means within columns sharing the same letter do not differ: Dunn's test (α = 0.05).
[b] One-way ANOVA found marked site effects for plastron length ($F_{5,588}$ = 18.3, P < 0.001). Means within columns sharing the same letter do not differ: Tukey's test (α = 0.05).
[c] Values sharing the same letter are not different: individual 2-tailed z-tests of proportions (α = 0.05).

a mark-recapture estimate of 1210 females populated the site in winter 2004 (normal 95% C.I.: 684–1737; Seber 1973). Males were excluded from the estimate because no males were recaptured. However, based on the 2004 sample sex ratio of 0.744 *pf*, the estimate increases to 1613 when males are included. Based on capture rates, populations at two other hibernacula, Janes Island in 2004 and 2005 and South Marsh Island in 2005 (Fig. 3), likely exceeded this estimate.

Size characteristics.—Off-shore sample sites near Bloodsworth, Smith, and South Marsh Islands, had slightly heavier females than the near-shore sites of Janes Island and the Nanticoke River (Table 2). The largest females were at the St. Jerome site and the smallest at the Nanticoke River, a site of frequent harvest. Similarly, the mean mass of adult males (all >9 YOA) was highest for off-shore Smith Island–S/Bloodsworth Island sites and lowest for near-shore Janes Island (Table 2). As essentially all males are immune to commercial harvest by virtue of their small size, Nanticoke River males ranked comparatively higher in site-specific mean mass (third) versus the females captured there that ranked sixth (last). For the six Tangier Sound sample sites, site-specific mean mass of males and females was not correlated (Spearman rank *r* = 0.54, P > 0.05, 4 df). Consistent with the known dimorphism in the species, the mean mass of female terrapins (1276 g, N = 767) was about three times greater than that for males (401 g, N = 399). Only 4.6% of females (35 of 767) fell below a PL measurement of the largest male (138 mm).

Effects of crab pot bycatch.—We tested for the effect of selective crab pot mortality on female size and found female PL to be greater in pot versus no-pot zones (one-way ANOVA: $F_{1,593}$ = 47.7, P < 0.001; mean PL, pot zone = 179.6 ± 0.61, N = 366; mean PL, no-pot zone = 172.9 ± 0.73, N = 229). Because the male PL distribution was found to be non-normal, we applied the Kruskal-Wallis ANOVA test on ranks and found a larger median value in pot versus no-pot zones (*H* = 25.6, P < 0.001, 1 df; pot zone median PL = 117, N = 183; no-pot zone median PL = 114, N = 186). Site-specific tests showed a marked pattern of larger PL means at sites with crab potting that produced a consistent alignment of ranks to pot and no-pot zones (Table 3). We also found females to have a higher proportion of young ≤10 YOA in no-pot versus pot zones (one-way ANOVA: $F_{1,13}$ = 5.2, P < 0.04; mean proportion no-pot zone = 0.26 ± 0.13, N = 8; mean proportion pot zone = 0.11 ± 0.11, N = 7). Individual site-specific tests produced a

similar pattern of a higher proportion of females at sites in no-pot zones with a consistent alignment of ranks to pot and no-pot sites (Table 3).

Testing for acute effects.—On initial placement of the 24 terrapins in the holding cage, three individuals were active enough to swim to the top of the water column. This indicated that their metabolism had increased enough to become active swimmers, but none were observed to breathe air at the surface. The swimming activity ceased shortly after placement suggesting that any increase in body temperature and metabolism was quickly reversed by return to cold water. All other terrapins were less active and simply sank to the bottom of the cage. Following the three-week holding period in February 2005, all terrapins were alive and observed to behave normally, i.e., were sluggish but active; there was no sign of morbidity.

DISCUSSION

Our discovery that upwards of a thousand or more terrapins can be concentrated at heavily populated hibernacula underscores the vulnerability of the species to winter scrape harvest. Our capture of 160 terrapins/h at South Marsh Island demonstrates how, in certain instances, hundreds of terrapins can be removed from a local area in a matter of hours, a majority of which would be harvest-size females. Because terrapin population traits include low recruitment, delayed maturity, long life, and limited dispersal (Gibbons et al. 2001; Harden et al. 2007; Tucker et al. 2001), high survival of long-lived adults is critical to sustaining populations (Mitro 2003). It follows that harvest removal of a large portion of breeding-age females would be devastating to local populations. Terrapins, like other long-lived turtles, have no compensatory means to replace such losses (Brooks et al. 1991; Congdon et al. 1993; Heppell 1998) and recovery would be predicted to be especially protracted.

As estuarine bay hibernacula have never been studied previously, no comparative data exist on numbers, size, and sex ratios. Moreover, we have no knowledge of how our capture characteristics have been altered by the confounding influence of two principal anthropogenic effects: 1) the direct loss of females to commercial harvest and 2) selective mortality of small terrapins as bycatch in crab pots (Roosenburg et al. 1997; Roosenburg 2004). Because our data show that heavy terrapin harvest would quickly devastate the adult female portion of the population, the prevalence of a female biased sex ratio in Tangier Sound is strong evidence of minimal harvest activity in the region in the recent past. Terrapin mortality in recreational (not commercial) crab pots primarily affects smaller terrapins (males and young females) that occupy habitats near shore where they are at risk to recreational crab pots (Roosenburg et al. 1997; Roosenburg 2004). Terrapin exposure and subsequent mortality in commercial crab pots in Tangier Sound therefore seems mediated by virtual restriction of commercial pots to offshore use. Indeed, Roosenburg (2004) suggested that Maryland's deep-water restriction on commercial crab potting likely has averted the decimating losses to Bay terrapin populations such as have been reported in Florida (Seigel 1993), South Carolina (Dorcas et al. 2007; Gibbons et al. 2001; Hoyle and Gibbons 2000; Tucker et al. 2001), and more recently, Georgia (Grosse et al. 2009). Nonetheless, decades of crab pot exposure seem apparent as our results indicate an effect of increased size of both sexes and reduced number of young females. These results are consistent with demographic effects attributed to selective crab pot mortality in tidal creeks of the Kiawah River, South Carolina (Dorcas et al. 2007), and at the Goodwin Islands at the mouth of the York River, Virginia (Wolak et al. 2010). Although other interpretations are possible, a non-normal PL distribution for males, in contrast to a normal distribution for females, lends support to an active mortality process affecting males. Additionally, and most significantly, we found the proportion of young females in the no-pot zone to be 2.4 times that in the pot zone. It follows that this apparent loss of females to crab pots, and the projected loss in recruitment it represents, would have the greatest long-term effect on terrapin productivity in Tangier Sound.

Our winter sampled sex ratios and the sex- and age-related vulnerability of terrapins to crab pots also may be driven by a fundamental distribution process related to size, i.e., larger terrapins dominating open-water estuarine bays and smaller terrapins seeking protected areas in tidal creeks and interior salt marsh. Roosenburg et al. (1999) provide evidence of larger adult females moving farther and spending more time offshore while smaller males and juveniles remain in near-shore shallow water. Findings from our summer captures at Smith Island support this notion as our interior salt marsh bait-trap captures yielded smaller terrapins of more even sex ratio (0.58 *p*f) and open-water Bay-shore fyke net captures produced primarily large females (0.87 *p*f; P. Henry, USGS, pers. comm.). That terrapins overwinter in interior tidal creeks and creek banks also has been documented (Yearicks et al. 1981). Our samples show that few females <6 YOA (with mean PL of 134 mm and mean mass of 560 g) and few males <6 YOA (mean PL of 105 mm and mean mass of 300 g) occupy estuarine bays in winter.

The comparatively pristine nature of Tangier Sound, in contrast to highly developed areas of the Bay, likely provides resilience to terrapin populations, as evidenced by our estimated female recruitment rate of 4–7%. This recruitment level seems favorable and sets a bench mark for future winter sampling, but its relation to population status is unclear without knowledge of other vital population statistics, especially an estimate of population growth rate (Mitro 2003). Further demographic study is needed to better establish the status of Tangier Sound terrapin populations.

Although terrapins were generally abundant in Tangier Sound, the paucity of numbers in St. Jerome Creek, a former harvest site, is enigmatic. The loss of terrapins at this formerly productive site may be related to harvest or perhaps a broader population decline documented during long-term

study of terrapins on the nearby Patuxent River (W. Roosenburg, Ohio University, pers. comm.).

CONCLUSIONS

The nature of adult female terrapins to aggregate in hibernacula often in high densities and in easily accessible estuarine bays has made them exceptionally vulnerable to commercial winter harvest. Such harvest, if unregulated, can be devastating to local terrapin populations. Although no exact history can be reconstructed, winter scrape fishing may have played a part in the near extirpation of the species in Chesapeake Bay in the early 20th century (Carr 1952; Ernst and Lovich 2009; McCauley 1945). In 2007, a well-organized conservation movement successfully lobbied the Maryland legislature to permanently close the terrapin fishery. Commercial harvest of diamondback terrapins is now prohibited throughout Chesapeake Bay.

Now that the commercial terrapin fishery is closed, adopting scrape fishing as a winter sampling method could be of particular value in assessing the past effects of harvest and recovery of terrapin populations. Scrape fishing of hibernacula offers unique access to a large portion of the adult female segment of the population, including females approaching breeding age. Moreover, scrape sampling offers a novel means to advance scientific study of terrapins in winter, an aspect of the biology of the species that has been little addressed. In this light, we recommend further work be conducted to better understand physiological effects of removal from hibernacula and effects on long-term survival. We believe winter scrape sampling could be an important element of terrapin population and scientific study in Chesapeake Bay and perhaps elsewhere throughout the north temperate range of the species.

Acknowledgments.—This study could not have been conducted without the boating skills and special knowledge of terrapin hibernacula and harvest methods provided by Smith Island resident D. Marshall. His willingness to share his intimate knowledge of terrapins has made this a very special experience. Additional thanks go to W. Roosenburg for assisting with marking techniques and freely sharing his special knowledge of terrapins from his extensive research on the Patuxent River. Additional thanks are extended to C. Driscoll and K. Brittingham for field assistance and N. Beyer, M. Erwin, E. Grant and W. Link for review of an early draft of the manuscript. Animal welfare protocols used herein were detailed in a peer-reviewed study plan and approved by the USGS Patuxent Wildlife Research Center's Animal Care and Use Committee.

A Large-Scale Snake Mortality Event

Road mortality has been shown to constitute a considerable threat for a variety of herpetofaunal species. A number of possible explanations for movement onto or across roads resulting in mortality have been proposed, including seasonal movements between habitats (Bernardino and Dalrymple 1992; Smith and Dodd 2003), seasonal dry-down of suitable habitats (Aresco 2005; Bernardino and Dalrymple 1992; Enge and Wood 2002), desire to access resources on the other side (Andrews and Gibbons 2005), movement to new areas for breeding (Lebboroni and Corti 2006), and movement and foraging following rainfall events (Ashton and Ashton 1988; Carr 1963; Cook 1983; Gibbons and Dorcas 2004; Tennant 1997).

In addition to the hazards of entering or attempting to cross roads, it appears that aspects of snake natural history may put them at a greater risk of road mortality than other herpetofaunal species. Snakes are known to use warm road surfaces for thermoregulation (Bernardino and Dalrymple 1992; Enge and Wood 2002; Rosen and Lowe 1994). Andrews and Gibbons (2005) report that snake roadkill may be magnified by immobilization behavior with some snake species stopping on the road during crossing. Some authors have suggested that snakes are commonly intentionally targeted by drivers (Ashley et al. 2007; Rudolph et al. 1999; Shepard et al. 2008).

In March of 2006, we observed a snake roadkill event along a newly opened road leading into the Southwest Florida International Airport located in Fort Myers, Lee Co., Florida, USA (26.5123°N, 81.7726°W). The airport developed a new terminal, which included the opening of this new road to the public in September 2005. The initial report of a snake roadkill event came from observations taken on 12 March 2006, suggesting that the majority of dead-on-road (DOR) snakes were killed during the preceding week (5–11 March). The observations were made along 1.5 km of the new airport access road; no snake carcasses were found before or after this section of the road. We documented this large-scale snake roadkill event, which appears to have been greater in magnitude and density than any other snake mortality event reported in the literature for this small of an area for this short of a time period (Beck 1938; Hellman 1956; Smith and Dodd 2003), with the exceptions of mass snake roadkill events associated with a hurricane (Carr 1963) and a snake migration event (Tennant 1997).

Methods.—The airport expansion included construction of a new four-lane roadway and creation of a canal (Figs. 1A and 1B). The roadway consisted of both an east and westbound terminal road with a grassy median separating them. The speed limit was 45 mph. Bike paths were located exterior to the roadway and had a width of 1.6 m as compared to a single road lane width of 3.6 m. Grassy shoulders were located exterior to the bike paths. The southern shoulder extended 10–12 m to a low (0.5 m) berm which separated the shoulder from a 20–25 m wide stormwater treatment swale. A second berm (1.5 m high and 15 m wide), located south of the swale, ran parallel to the canal which was approximately 15 m in width.

From 19–22 March, 2006, 1.5 km of the eastbound terminal road (Fig. 1B) heading towards the Southwest Florida International Airport was walked and snake species were recorded. The road was divided into 10 m segments. The location of each roadkilled snake along the eastbound side was recorded as follows: in the left hand lane of the road near the median, in the right-hand lane of the road near the bike path, on the bike path, or on the grassy shoulder. The area of grass along the road edge that could be reliably observed

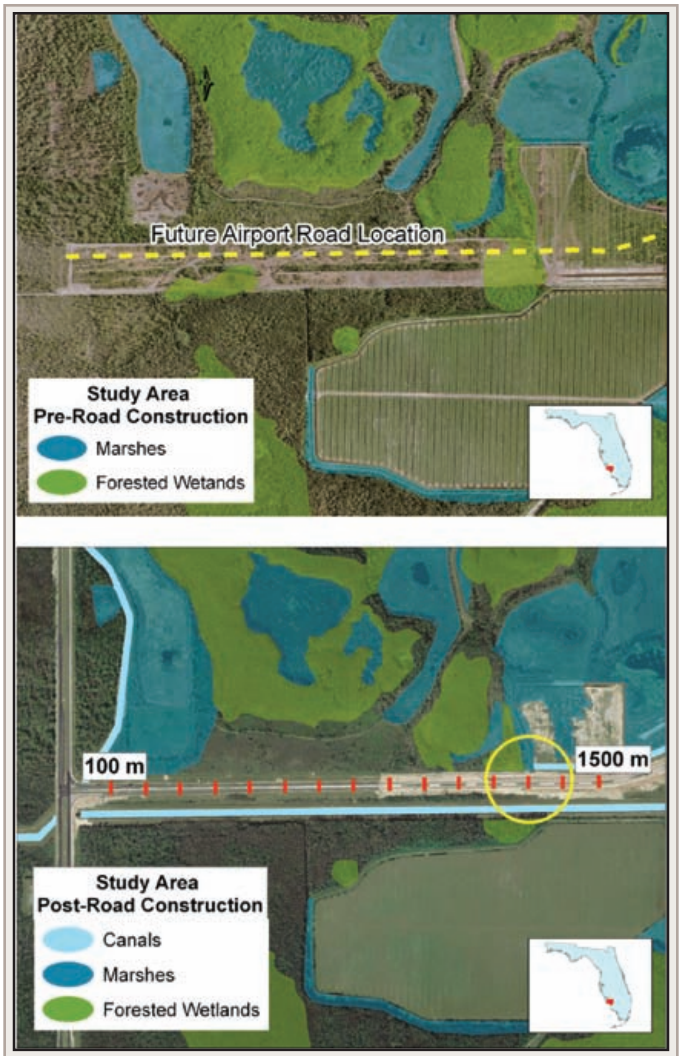

FIG. 1. A) Aerial photograph taken April 2002. B) Aerial photograph taken January–February 2005. Locations of the 100 m points along the road are indicated. The circled area represents road segments 12–14, where the highest proportion of DOR snakes occurred.

was approximately equal to the width of a single lane. Each 10 m road segment was visited only once during the four day sample. After each sampling event, the west-bound side of the road was carefully searched for carcasses, but no DOR snakes were located. If possible, DOR snakes were identified to species. No effort was made to sex the snakes, but immature individuals were distinguished. All snakes were categorized as "old" (dried or with considerable decomposition) or "new" (with moist, flexible body tissues, and assumed to have been killed within the previous 24 h). If any of the "old" snakes could not be identified due to extensive decomposition, they were recorded as an unidentified species.

We summarized the data for the entire sample and combined the data into 100 m road segments in an effort to identify a corridor for future protection. We tested for significant differences in position along the 1.5 km of the road length and for differences on the areas of the road (right lane, left lane, bike path, shoulder) using the single classification Goodness of Fit Test, with expected frequencies defined by relative areas (Sokal and Rohlf 1981) using SPSS Version 16.0 for Windows ($\alpha = 0.05$).

Results.—A total of 395 DOR snakes were recorded during the surveys. Of the species identified, *Nerodia fasciata pictiventris* was observed the most often (N = 140), almost double the amount of the next closest species, *Thamnophis sauritus sackenii* (N = 75). Other species identified include *Thamnophis sirtalis sirtalis* (N = 29), *Agkistrodon piscivorus conanti* (N = 15), *Storeria victa* (N = 4), *Pantherophis guttatus* (N = 1), and *Regina alleni* (N = 1). A large number (N = 130) of unidentified individuals were also recorded. Eight immature snakes were recorded, representing 2% of the DOR carcasses. Two live snakes were observed attempting to enter the road during our surveys, one of which was removed from the roadway, while the other was struck by a vehicle and killed. In addition, sixteen carcasses (4%) were scored as 'new,' thereby indicating that the event was a prolonged period of snake movement and mortality during the second and third weeks of March 2006. Six DOR frogs and two DOR turtles were also recorded.

The most DOR snakes were observed in road segments 12–14 (1200–1400 m) (Fig. 2). These segments exhibited significantly higher numbers of roadkilled snakes than other segments ($G = 177.4$, $P < 0.001$). Of the snake species observed, only five individuals were found in the left-hand lane. There were 116 individuals discovered in the right lane, and 77 in the bike path. The most individuals (N = 197) were found in the grassy shoulder. This distribution is significantly different than random ($G = 237.5$, $P < 0.001$). All three of the species with sample sizes large enough to allow for individual tests (i.e., *Nerodia fasciata pictiventris, Thamnophis sauritus sackenii,* and *Thamnophis s. sirtalis*), as well as the unidentified snake carcasses, showed significantly greater distributions toward the right-hand side of the road ($P < 0.001$ in all four tests).

To explore a possible weather-related explanation for the snake movement, we examined the pattern of rainfall and temperature at the Southwest Florida International Airport during the month of March in recent years. Almost all of the measurable rainfall recorded in March 2006 was from a single rainfall event on March 23, which was after the roadkill event. During the second and third weeks of March 2006 (5–18 March), the mean minimum temperature at the airport was 16.1°C and the mean maximum temperature was 28.3°C. During this same period, nine days had temperatures above the mean daily maximum as compared to the two previous and two post years.

Discussion.—Several studies have found that reptile carcasses are more often located closer to the edge of the road than the center of the road. In 1950, an unusually large number (N = 478) of juvenile mudsnakes (*Farancia a. abacura*) were discovered along U.S. Highway 441 in Paynes Prairie, Alachua County, Florida, almost half of which were DOR (N =

223) (Hellman 1956). Of these, only 10–20 snakes were found in the western half of the road and its adjacent shoulder; the remainder were located in the eastern half of the road and its shoulder. Approximately 12 individuals were found on the eastern slope of the embankment. A study conducted in 1998–1999 on this same highway discovered that carcasses were distributed unevenly on the paved surface, with most being located in the outside lanes (Smith and Dodd 2003). In Lake Jackson, Leon Co., Florida, 95% of turtles were killed as they first entered U.S. Highway 27 adjacent to the shoulder, and the remaining 5% were killed in the first two traffic lanes (Aresco 2005). A similar pattern was discovered in a road impact study conducted on a major road in Tuscany (Scoccianti 2006), with most of the reptile remains found very close to the edges of the road, and less frequently in the middle of the road.

Based on results from the aforementioned studies, it can be assumed that most reptiles are killed as they first enter a highway. This indicates that a majority of the snakes in our own study entered the highway from the south, and were hit as they first entered the east-bound lane of traffic. We assume the snake carcasses found on the bike path and in the grass were actually struck on the road, and the snakes attempted to move to safety after being injured. As seen on the aerial photograph (Fig. 1B), the wetland system located south of the newly opened road ends around road segment 13 (1300 m). It appears that the snakes may have followed the natural landscape to the east, which in effect funneled snakes onto the roadway when the wetland ended. This could explain why a majority of DOR snakes were found between road segments 12 and 14. Beyond road segment 15, the roadway curves north and the area between the shoulder and the canal berm rapidly expands to over 100 m in width.

Although we speculate that the snakes were attempting to cross the road to reach wetlands on the other side, the results may also suggest that snakes might have been moving onto the road to thermoregulate. The road surface in this study is comprised of asphalt. Shine et al. (2004) documented that during the day, mean substrate temperatures are similar on asphalt road surfaces as to those on surrounding surfaces (i.e., grass, dirt, and gravel). However, after sunset, the asphalt surface of the road is substantially warmer (4–9°C) than other surfaces. Since asphalt holds more heat than other surfaces, it is likely that the asphalt road surface leading into the airport warmed during the daytime and held the heat after sunset, thus attracting snakes to the roadway to thermoregulate. Because March 2006 was dry and had several warmer than mean daytime temperatures, with some cool nights, it is possible that most snakes were killed on the road after sunset as they attempted to warm themselves on the roadway.

It is possible that some snakes were not included in the survey count due to the presence of scavenging animals (e.g. crows [*Corvus* sp.], Raccoons [*Procyon lotor*], etc.) and/or fast deterioration due to the climatic conditions of southwestern Florida. Other studies have found that the number of DOR

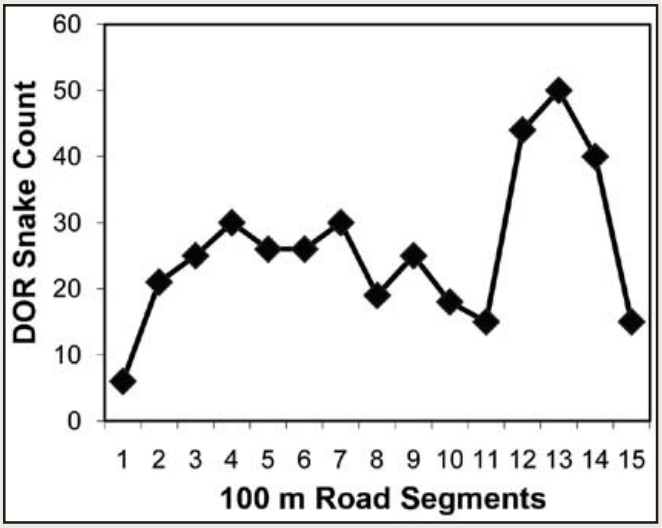

FIG. 2. Count of DOR snakes along road. Data were combined for 100 m segments of the road, from west to east. Counts include only confirmed snake carcasses.

individuals recorded is actually an underestimate of the true number killed (Bernardino and Dalrymple 1992; Enge and Wood 2002; Hels and Buchwald 2001; Smith and Dodd 2003). Even with possible underestimation of the magnitude of this event, the snakes counted in this survey constitute the most numerous mortality event for this spatial scale (1.5 km) reported in recent literature, and presumably comprised a significant portion of the snake community in the associated wetlands.

There are several potential ways to avoid mortality events such as this in the future. Aresco (2005) found that a drift fence system connected to existing drainage culverts significantly reduced road mortality of turtles. The fence physically prevented access to the roadway and directed the turtles through culverts beneath the road. Similarly, Scoccianti (2006) described a drift fence installed along both sides of a road in combination with a viaduct constructed by raising the road. Bernardino and Dalrymple (1992) discussed several options available to decrease the rate of road mortality, including the construction of wildlife underpasses, temporary closing of roads on main migratory nights, and installation of reduced speed zones. Smith and Dodd (2003) described the construction of a barrier wall and underpass system. Because not all of these strategies may be an option due to cost or impracticability, mitigation efforts should be restricted to those areas identified as important travel corridors or as connections between areas of significant habitats (Jackson 1999).

Future research should include quantifying roadkill dynamics following road construction or landscape modification where snake populations may be displaced and concentrated. These conditions appear to create the opportunity for large-scale roadkill events, and may require mitigation efforts. Because this snake mortality event only occurred along the portion of the road that was adjacent to the newly created

canal, future studies should focus on similar types of road development. The construction of the roadway and the canal impacted forested wetland habitats; most of these impacts occurred between road segments 12 and 13 (Fig. 1B), which is also where a majority of the snake mortality took place. Further studies should be conducted to determine if this was a unique event, or if this is a common occurrence for this type of road development. If a trend is discerned, planning for future transportation infrastructure could more effectively focus on minimizing and mitigating impacts to these critical areas (Jackson 1999). The success of any mitigation efforts should also be carefully monitored.

Acknowledgments.— The authors appreciate the Lee County Port Authority allowing us access to the site. We acknowledge the help of Lucas Everham and Zachary Wohlpart during data collection. We thank Phil Allman, Marty Main, Kristin Wood, Nathan Nazdrowicz, and Chris Stafford for their comments on initial drafts of the manuscript. We would also like to thank Kenney Krysko and two anonymous reviewers for their thoughtful comments, which helped us to place this event in a larger context and greatly improve this manuscript.

Using a Portable Reader for Non-invasive Detection of PIT-tagged Skinks Under Coverboards

A variety of methods exist for uniquely marking animals for mark-recapture studies. Due to its directness and accuracy, the mark-recapture method is an effective technique used to assess demographic parameters and life history and behavioral data such as density, survivorship, growth rate, and individual patterns of space use and social behavior (Fox and Shipman 2003; Hokit and Branch 2003; Tinkle et al. 1993). For lizards such as North American skinks, which are often secretive, delicate, cryptically colored, and difficult to capture, demographic studies can be problematic and produce incomplete and unsatisfactory results due to lack of recaptures (Cavalieri 2010; Somma 1985). Coverboards are the most reliable way to repeatedly observe such skinks (Cavalieri 2010; Sutton et al. 1999), but the success of actual capture using this method depends more on prowess than other techniques such as passive trapping. Thus, the family Scincidae, with the exception of a few species (Cooper 1999; Cooper and Vitt 1989, 1993; Fitch 1954), has remained an under-studied taxon in North America. Due to the difficulty of attaining recaptures and the risk of stress or injury to the lizard during hand capture, we strove to develop an alternative methodology to augment relocations of marked individuals.

Passive integrated transponders (PIT tags) are often used as a backup or alternative to toe-clipping, scale-marking, or other traditional marking techniques (Ferner 2007; Gibbons and Andrews 2004). The use of subcutaneously-implanted PIT tags in mark-recapture studies offers the unique advantage of a system of internal, permanent identifiers that are completely unambiguous if read correctly from the scanner (Gibbons and Andrews 2004; Hill et al. 2005).

The purpose of our study was to evaluate the performance of a modified PIT-tag system by determining: 1) the greatest distance at which a PIT tag can be read, both on the surface and under coverboards, 2) the effect of antenna orientation, and 3) the effects of experience level and fatigue of field workers on detection of field-employed PIT-tags.

FIG. 1 Horizontal and vertical orientation of the antenna hoop and illustration of how to scan a coverboard with PIT-tag reader.

Materials and Methods.—Our study site, located in mixed-grass prairie in Payne County, Oklahoma, USA, was a 1-ha grid with 100 1.22-m × 0.61-m × 1.91-cm coverboards placed at the centers of the 10-m × 10-m cells. The soil was a well-drained silty clay loam with native prairie and old field grasses and approximately 4 cm of thatch.

We modified a Destron Fearing Portable Transceiver System (model 2001F-ISO, Biomark, Inc.) by mounting the racket antenna on a PVC pipe (Fig. 1). To prevent interference with the antenna, we used all non-metal construction. We

glued a T-joint to a 45º elbow joint and attached this section to a 1.22-m PVC pipe (2.54 cm diameter) that served as a handle. We drilled two holes perpendicular to the elbow joint and passed the racket antenna through the opening in the T-joint so that the hoop portion was facing away from the opening of the 45º elbow joint. We threaded a plastic zip tie through each hole and the internal opening of the racket antenna and secured it to prevent the antenna from sliding forward out of the handle. We suspended the transceiver upside down from a belt in a harness to allow the person wearing it to easily read the display. We used 8.5-mm × 2.12-mm, 134.2-kHz ISO, 0.067-g glass-encapsulated, implantable passive integrated transponders from Biomark, Inc.

We first determined the maximum horizontal range at which a PIT tag could be read when placed on the ground and holding the antenna 4 cm above the substrate using two different orientations of the antenna hoop (Fig. 1): horizontal orientation (i.e., the opening of the hoop parallel to the ground) and vertical orientation (i.e., the opening of the hoop perpendicular to the ground). We determined reading distance by setting the transceiver to continuous scan and holding the antenna stationary while moving a PIT tag along a wooden measuring stick lying on the ground until the serial number registered. The point on the measuring stick at which the number was first read was the maximum horizontal reading distance at 4-cm height. We performed two sets of trials, one with the PIT tag in a plastic microcentrifuge tube and one with the PIT tag subcutaneously implanted into a Great Plains Skink (*Plestiodon obsoletus*) held in a mesh bag. We conducted 20 repetitions of each set at the study site, using a freshly charged transceiver for every repetition.

Because the horizontal antenna orientation gave the greatest horizontal reading distance in the trials above (see Results), we then determined the maximum vertical distance at which a PIT tag could be read through a coverboard with the antenna in the horizontal orientation. As before, we separately scanned a PIT tag in a microcentrifuge tube and a PIT tag implanted in a skink. We placed a tag under a coverboard (1.22 m × 0.61 m × 1.91 cm) and then held the antenna by the handle 1.37 meters above the coverboard, moving it in the horizontal orientation slowly down the wooden measuring stick until the tag registered. The vertical distance from the point at which the tag first registered from the lower edge of the antenna hoop to the surface of the coverboard was the maximum vertical reading distance. As before, we conducted 20 repetitions of each set, using a freshly charged transceiver.

In order to assess the accuracy of the PIT-tag reader system, we placed each of 20 PIT tags in microcentrifuge tubes under 20 randomly selected coverboards in a set of 100 in the field and recorded the serial number for each tag. We assembled two groups of volunteers: experienced (N = 7), those who had used the PIT-tag reader two days a week from May to August 2008 in this fashion, and novice (N = 10), those who had no prior experience with PIT-tag readers. We gave each isolated volunteer the antenna mounted on the handle with the transceiver in the holster, a clipboard, a pencil, a datasheet to record the serial numbers and location of detected PIT tags, and a demonstration of how to scan a coverboard and read the serial numbers. Each volunteer stood and passed the antenna in a serpentine pattern over each coverboard as closely as possible without touching it while holding the antenna in the horizontal orientation, record the serial number if a tag was detected, and then proceed to the following coverboard until all 100 coverboards were scanned in order. Each volunteer scanned coverboards while alone at the study site with no other volunteers observing, and was given unlimited time to scan coverboards.

We tested the following null hypotheses: 1) all tags have an equal chance of being found, 2) the success of finding tags is independent of experience level, and 3) the likelihood of finding tags does not vary with increased search time per coverboard. We used a Chi squared goodness-of-fit test to determine if all tags had an equal chance of being found, and a Chi-squared heterogeneity test to compare level of experience with success at finding tags. We used a linear regression of number of tags found vs. average duration of search per coverboard to determine if the likelihood of finding tags varied with increased search time per coverboard.

Results.—The maximum horizontal distance beyond the outside of the antenna hoop at which a PIT tag was read with the antenna held 4 cm above the ground in the horizontal orientation for a PIT tag in a microcentrifuge tube and for a PIT tag implanted in a skink was mean = 4.13 cm ± 1 SD of 0.55 and mean = 3.88 ± 0.70, respectively. In the vertical orientation, the maximum horizontal distance for a PIT tag in a microcentrifuge tube and for a PIT tag implanted in a skink was mean = 2.08 cm ± 0.60 and mean = 2.08 ± 0.81, respectively. The maximum vertical distance at which a PIT tag was read in the horizontal orientation through a coverboard for a PIT tag in the microcentrifuge tube and for a PIT tag implanted in a skink was mean = 13.10 cm ± 2.00 and mean = 12.24 ± 2.77, respectively.

The horizontal antenna hoop orientation allowed a greater range for detecting PIT tags than the vertical orientation, and a PIT tag enclosed in a microcentrifuge tube had approximately the same maximum read distance as a PIT tag implanted in a skink. Therefore, during the next portion of the experiment, we treated centrifuge tubes as skink surrogates and had volunteers use the horizontal antenna orientation to find PIT tags randomly placed under coverboards. The mean proportion of tags found was 71.8% and all tags had the same chance of being found (χ^2 = 4.85, *df* = 19, P = 0.999). Experience level affected ability to find tags (χ^2 = 5.37, *df* = 1, P = 0.020), with experienced readers finding 65% and novice readers finding 76.5% of tags. The likelihood of finding tags did not vary with increased average search time per coverboard (r^2 = 0.058, $F_{1,15}$ = 0.930, P = 0.350).

Discussion.—All tags had the same chance of being found. This indicates that there was no bias for tags under different

coverboards, suggesting that this is a good methodology for augmenting relocations of secretive, partially fossorial animals that are difficult to recapture.

Experience affected ability to find tags, but in an unexpected way. Novice readers found more tags than experienced readers. This is possibly because novice readers followed directions more thoroughly than experienced readers who had more confidence in their abilities and a *laissez-faire* attitude toward the process. Blomquist et al. (2008) made a similar comparison between an observer informed of the location of the tags and an uninformed observer, with PIT tags placed underground. The informed observer found more tags in one pass than the uninformed observer did with 3 passes though the study area. This is not directly comparable to our study because experience with the technique differs from actual knowledge of the location of the tags; however, our volunteers did know that PIT tags were only under coverboards, which helped focus their searching. We suggest that fieldworkers can find tags more easily when given a focal object, e.g., a coverboard, than when searching broadly in the field. The likelihood of finding tags did not vary with increased search time. This indicates that this technique works well without the need for slow, intensive searching.

Traditionally, PIT-tagging relied on physically recapturing an individual in order to scan the tag. Recently, there has been an increase in the number of studies using automatic remote interrogation systems that do not rely on subsequent recaptures. Harper and Batzli (1996) used fixed hoop antennae and transceivers over vole runways in enclosures to remotely assess movement of individuals; over a period of four months, they were able to detect 1645 uses of runways (or remote PIT-tag recaptures) having marked only 893 animals. Boarman et al. (1998) marked 172 tortoises within 3 km of their automated interrogation system; only 5 tortoises were scanned for a total of 77 recaptures by PIT-tag identification. Gruber (2004) marked 29 animals and had 178 remote PIT-tag recaptures using antennae coiled around the bases of trees to determine the movement of PIT-tagged geckos. These systems are advantageous because they collect data continuously with reduced man-hours once the initial setup of equipment has been completed. The drawbacks of automatic remote interrogation systems include the need for a power supply and preventing theft of unattended equipment. Our system is a hybrid of traditional and automatic remote interrogation systems, with higher labor needs (as compared to completely automated systems) balanced by the ability to cover more ground and check more refugia.

Although there have been other studies using PIT-tag readers mounted on poles (Blomquist et al. 2008; Sasaki et al. 2009), none has used this method as a means of identifying animals under coverboards. Because we used a commercially available antenna, our system is easier to implement than others (Blomquist et al. 2008; Gruber 2004; Zydlewski et al. 2006), and may represent a useful tool for mark-recapture studies of small reptiles that commonly use cover objects.

Acknowledgments.—Funding was provided by Southwestern Association of Naturalists, Sigma Xi, American Museum of Natural History, Bob and Julia Bollinger, and the Oklahoma State University Graduate Student Society. We thank the Stillwater Regional Airport for access to land. This project was approved by the OSU Institutional Animal Care and Use Committee (AS074). A New Rapid Assessment Technique for Amphibians: Introduction of the Species List Technique from San José de Payamino, Ecuador

The urgent need for baseline amphibian data in light of global population declines (Stuart et al. 2004) has led to a call for accurate and robust rapid assessment techniques for amphibian assemblages. This is especially pertinent in areas such as wet tropical rainforest where there is a scarcity of data (Duellman 2005; Gardner et al. 2007) and where robust and comparable data are particularly required to underpin difficult management decisions. The lack of amphibian data from wet lowland forest habitats is often a result of the logistical problems of conducting research in such areas (Doan 2003; O'Dea et al. 2004; Poulsen et al. 1997) where dense understory vegetation, inaccessible terrain, extreme rainfall and humidity, and seasonality (Doan 2003) hinder research. High species diversity and clustered distributions further complicate surveying (O'Dea et al. 2004; Poulsen et al. 1997). Amphibian survey methods used in temperate climates are not applicable to the rainforest environment in many instances (Doan 2003). This, coupled with the fact that rainforest inventorying is often abbreviated due to both the urgency of conservation concerns in the tropics (O'Dea et al. 2004; Heyer et al. 1994; Poulsen et al. 1997; Poulsen and Krabbe 1998) and by cost (Doan 2003; O'Dea et al. 2004; Pellet and Schmidt 2005), points to the need for amphibian rapid assessment techniques specifically designed for work in the difficult tropical rainforest environment (Doan 2003; Poulsen et al. 1997).

The aim of this paper is to introduce the Species List Technique (SLT) (MacKinnon and Phillipps 1993) as a rapid assessment technique for inventorying amphibian assemblages in tropical rainforest environments. We discuss the suitability of this technique to assess species richness and species accumulation. Results are compared over short (21 day) and longer (48 day) time periods to allow assessment of effectiveness in a rapid assessment context. Impact of the methods on the habitat and fauna, plus time and financial costs are also considered qualitatively. A set of standardization suggestions are made to ensure comparability between studies.

The Species List Technique (MacKinnon and Phillipps 1993) was designed for rapid assessment of avifauna especially in tropical rainforest environments (O'Dea et al. 2004; Poulsen et al. 1997). This straightforward technique is standardised to provide an index of effort for opportunistic encounters, meaning no data are excluded from analysis (O'Dea et al. 2004). Cumulative species richness is related to the number of observations, rather than space or time, allowing for moderate differences in field technique and observer experience (Herzog et al. 2002). This standardization makes the SLT much more valuable for species assemblage comparisons between studies and sites than species inventories alone (Herzog et al. 2002). The time efficiency of the method, through constant data collection while in the field, lends itself for use in a rapid assessment setting.

All species seen or heard are recorded in species lists of predetermined length. The number of species recorded per list is chosen to reflect species richness. Lists of 8 to 20 species have previously been used for bird surveys (Bibby et al. 1998; Herzog et al. 2002). Different geographic areas can only be compared when species lists of the same length have been used. Therefore, it is important that standard amphibian list length should reflect species richness of all tropical areas where the SLT may be used. We assessed the use of lists of 3, 5 and 10 species for our amphibian survey in order to provide a balance between robust sample size for formation of species accumulation curves and comparability between sites of varying richness. The lower the number of species in a list, the more the shape of the accumulation curve (and therefore

the species richness prediction) varies depending on sample size (Herzog et al. 2002). However, a high number of species per list will reduce the number of lists compiled and thus the accuracy of the accumulation curve. We found that the number of lists formed using 10 species lists was low (25 lists) and in less diverse tropical regions insufficient data may be collected to create an accumulation curve. Both 3 and 5 species lists gave a large enough sample size to create species accumulation curves. Therefore, based on Herzog et al.'s (2002) conclusion that longer species lists give more robust accumulation curves, we chose to use 5 species lists.

Species List Technique list formation begins when the first individual is observed. Each subsequent species (not individual) is added to the list until 5 species have been observed. Once a list is complete, a new list is started. Species can be repeated between, but not within, lists (Fig. 1). List formation continues throughout the length of the data collection period. Any species that cannot be immediately identified are assigned placeholder names until the species can be identified so that their order in the list is not affected. This data collection method has the key advantage that multiple observers can form their data into a single set of lists by recording the date and time each individual was observed to allow sequential addition of species to form lists during analysis, making time in the field as productive as possible.

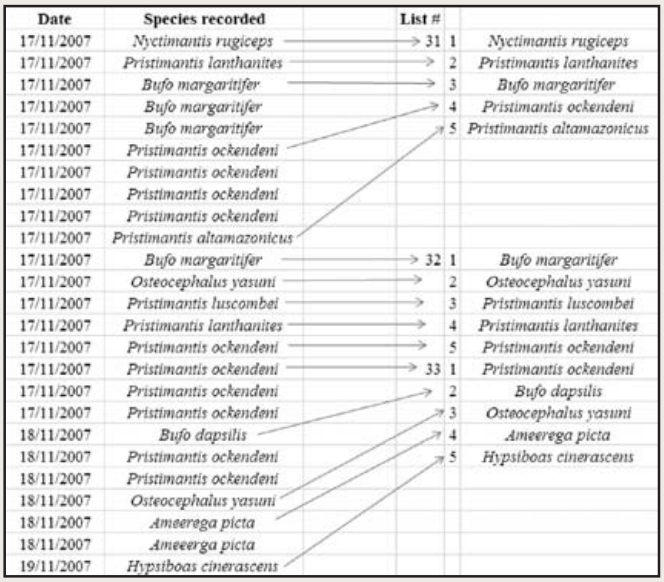

FIG. 1. An example of data collected in San José de Payamino and subsequent creation of Species Lists. Arrows highlight how individual observations are amalgamated into lists based on the order in which they are observed. Note that species are recorded only once per list regardless of number of individuals observed.

Data collection took place between June 2007 and May 2008 in the 27,000-hectare lowland tropical rainforest territory of the Kichwa community San José de Payamino, Orellana Province, Ecuador. Three sites within this territory (Sacha huasi, Bigay, and Paushiyacu) were each visited three times in one year and data were collected over the period of a week at each site (three weeks per site in total). However, due to logistical constraints, data collection could not take place during every day spent at the sites. Therefore, the number of days spent in data collection varied between 4 and 7 days during the week spent at each site. The methods were assessed separately over a short term (1 week at each site, totalling 21 days of data collection) and longer term (3 weeks at each site, totalling 48 days of data collection) period.

Species were recorded during night visual surveys utilizing pre-existing transects, opportunistic daytime observations and identification of calls. Each of three sites contained five parallel cut transects, each 100 m in length, with 20 m separation between transects. Visual sweeps were conducted along each transect, 2 m either side and up to 2.5 m in height, including low intensity disturbance of leaf litter, rolling small logs and turning over leaves. Detectability differences among species due to visibility, size or volume of calling were partially addressed by this methodical searching during night transects as reflected by the fact that one caecilian species (*Oscaecilia bassleri*) and two salamander species (*Bolitoglossa altamazonica* and *B. peruviana*) were observed. However, biases due to detectability are of concern with, although not unique to, this method (Bibby et al. 1998) and care must be taken to limit this bias. Transects are not a pre-requisite for SLT data collection and it is possible to include targeted areas while in the field, for example high density sites such as breeding pools in order to catalogue as many species as possible. Targeting like this is important for species where there are detectability issues and is not possible in more rigid sampling methods (Herzog et al. 2002). Opportunistic daytime observations included any amphibians observed around camp and on forest walks that were not part of targeted searches. Once a week, the first five calls heard at dusk were identified by comparison with reference recordings (Read 2000). Species accumulation curves were constructed by plotting the cumulative number of species observed as a function of list number (Gotelli and Colwell 2001). Species accumulation curves can be used as an indication of whether sufficient sampling effort has been undertaken to catalogue the total species richness of the area (Bibby et al. 1998). Species accumulation curves can also be extrapolated to show whether expected total species richness varies between areas (O'Dea et al. 2004). Chao 2 (Chao 1987) was used as an estimator of species richness as it has been shown to be effective in areas where many species are rare (O'Dea et al. 2004).

During the short term collection period, 35 species were recorded using SLT, with this number increasing to 55 in the longer time period. The accumulation curves were used to quantify whether the study area had been comprehensively surveyed (Fig. 2). The species accumulation curves did not reach an asymptote over either the short or longer time period. Thus, the number of new species being recorded had not declined, indicating that the species inventory for this study site had not yet reached completion. This is a reflection of

the high amphibian species richness of San José de Payamino and the amount of effort needed to inventory such diverse areas. The Chao 2 estimator value of 41±10.74 for short term SLT is an underestimation of the total species richness and with a large standard deviation has limited accuracy. However, the longer term SLT Chao 2 value of 80.08 ± 0.24 is plausible given known species numbers in nearby lowland rainforest areas of Ecuador (84 amphibian species recorded in Jatun Sacha: Vigle 2008) and has a small standard deviation. Regression lines, extrapolated from the accumulation curves to give a prediction of total number of species in the area, gave predicted species numbers of 60.19 with the SLT long term trial and 60.45 with the SLT short term trial. These values, however, do not match with the Chao 2 estimate of species richness, which is much higher. This could be due to the large number of rare species, for which only one or two individuals were observed. Chao 2 has been shown to be a robust estimator in these circumstances (O'Dea et al. 2004). The prediction made by extrapolating the accumulation curves will be inaccurate due to the curves not having reached an asymptote (Gotelli and Colwell 2001). The SLT method has demonstrated that this area is not yet adequately inventoried and that amphibian surveying needs to continue in San José de Payamino. The complete number of species present is undoubtedly higher than the 55 thus far observed and the richness of this area needs to be accurately estimated before it can be compared with other sites. The high conservation value of this area has been shown by the amphibian species observed thus far. Further study must be undertaken for its full importance to be realized.

In light of amphibian sensitivity to habitat disruption (Gardner et al. 2007), it is important to consider the impact to the environment of any biological surveys. The Species List Technique requires no cutting of transects, and species searches can be carried out in any manner. Frequent disturbance to a site through having to repeat data collection at specified transects is avoided. If call surveys are included in list construction, site disturbance can be further decreased. Logistically, SLT needs little in the way of equipment, other than a notebook, ID guide and pencil, and therefore the expense associated with this methodology is negligible. Efficient data collection leads to rapid recording of species present, permitting more comprehensive, comparable inventories to be created during the time available. Personnel with a moderately varied range of experience can carry out data collection without creating bias (O'Dea et al. 2004) as richness is standardized in terms of number of observations rather than time. Therefore, sufficient time can be taken to ensure accurate identifications. This has obvious benefits to expeditions, where every member can take part in data collection, increasing the likelihood that an area will be comprehensively surveyed in the time available.

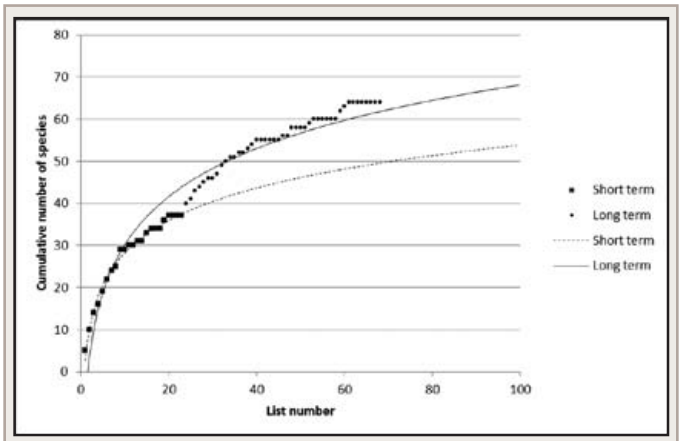

FIG. 2. Logarithmic species accumulation curves by list shown in terms of short or longer data collection periods. For longer-term data each curve represents the average value of 30 randomizations of sampling order and 10 randomizations for short term data. Logarithmic regression lines forecasted forward by 32 periods.

Standardization of SLT between users and sites will maximize comparability, a key benefit of the technique. Therefore, we recommend that five species lists are used for all studies. Researchers should ensure systematic as well as opportunistic searches to allow for differences in detectability between species. Species observations should also include day and night active species, as well as all habitat types within the area being surveyed to ensure comprehensive coverage. In seasonal areas, timings of surveys must also reflect activity periods of different species. Call surveys should only be carried out for areas where applicable reference recordings are available and the observer is confident in accurate identification. Areas should not be compared until they have been comprehensively surveyed, as assessed by reaching an asymptote in their species accumulation curve.

No single method will ever satisfy all scientific preferences and logistical constraints that befall field investigations (Doan 2003; O'Dea et al. 2004). Therefore, a compromise must be reached to take into account expense, environmental limitations, time constraints and the findings that can be taken from an investigation. When time is severely limited due to expense and the necessity for baseline biodiversity data in areas of conservation concern, then rapid assessment of a site is the best compromise (Heyer et al. 1994). The aim of this study was to assess whether SLT, previously only used to survey avifauna (O'Dea et al. 2004; Poulsen et al. 1997; Poulsen and Krabbe 1998), could be applied to amphibian assemblages. The Species List Technique facilitates rapid species inventorying alongside richness estimation, allowing standardized comparisons between areas where time for surveying is constrained. We therefore recommend the Species List Technique for the rapid assessment of amphibian assemblages in rainforest environments.

Acknowledgments.—We thank Roger Downie for offering his expertise and for reviewing the manuscript, and Stewart White for advice throughout this study. Thanks especially to Rachel Donnachie as well as Fraser Ross and Rafal Tusinski for their help with the

fieldwork, as well as all the Payamino guides who contributed, especially Lucio Cejua and Roberto Purraquilla. Thanks to the community of San José de Payamino who permitted us access to their territory and to the Payamino Project who facilitated and supported this work. Thanks to Twycross Zoo and the Royal Geographical Society (with IBG) for their fieldwork support. Fieldwork followed the University of Glasgow Amphibian Care and Use in Fieldwork and Laboratory Research Guidelines. We thank anonymous reviewers for their feedback on an earlier version of the manuscript.

Radio telemetry is extremely useful for studying habitat use and movements of free ranging snakes. Surgically implanting radio transmitters into the body cavity of snakes is standard practice in most studies (e.g., Reinert and Cundall 1982; Weatherhead and Blouin-Demers 2004), but this implanting method has its drawbacks. Surgery itself is risky for individual snakes because of the potential for infection or incomplete healing of the incision site. Also, transmitters that are small enough to be carried by small or slender snakes have a relatively short battery life and need to be removed or replaced often, thus requiring frequent surgeries. In rare or endangered snake species, the risk of using invasive implantation surgery may not be merited. External attachment methods are relatively non-invasive and allow removal and replacement of radio transmitters on smaller snakes. The Giant Gartersnake (*Thamnophis gigas*) is a semi-aquatic snake endemic to wetlands of the Central Valley of California, USA, and is federally and state listed as threatened (U.S. Fish and Wildlife Service 1999). Telemetry studies of the habitat use and movements of this species typically used surgically implanted radio transmitters, but this method is limited to larger snakes, primarily females, because of size requirements for surgery (> 250 g). To

FIG. 1. Radio transmitter attached to a *Thamnophis gigas* by the off-tail method using surgical tape.

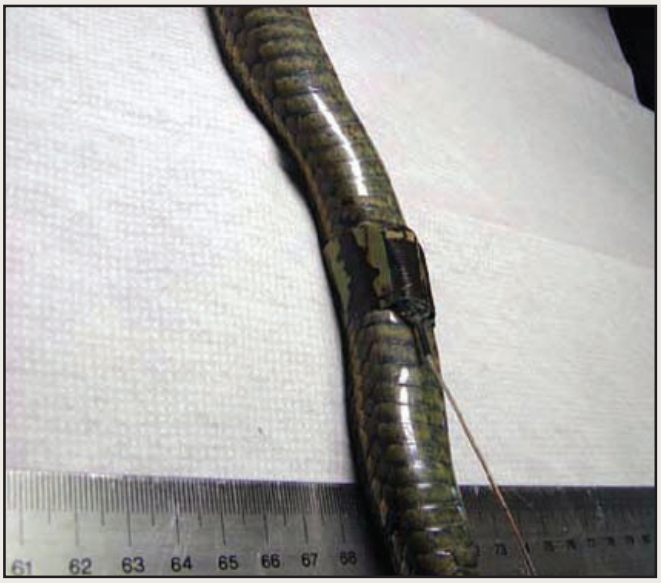

FIG. 2. Radio transmitter attached to a Thamnophis gigas by the body method using camouflage duct tape.

overcome difficulties and biases associated with radio telemetry of *T. gigas*, we developed and evaluated several alternative techniques to attach external radio transmitters using tape.

Materials and Methods.—We captured individual *T. gigas* by hand or in modified minnow traps (Casazza et al. 2000) at two sites in Colusa County (Colusa National Wildlife Refuge, 2003 and 2004, and Colusa Basin Drainage Canal, 2006). We measured, weighed, and marked each individual with a passive integrated transponder (PIT) tag in the field. In most cases, we attached transmitters to snakes while in the field and released them immediately after processing. However, if snakes appeared close to ecdysis, we held them in the laboratory until they shed. We taped transmitters to these snakes after shedding and released them at their capture locations as soon as possible.

We used 1.3 g radio transmitters (model R1620, Advanced Telemetry Systems, Inc., Isanti, Minnesota, USA), measuring 8 × 19 × 4 mm with a 10 cm whip antenna. The flat, oblong shape of this transmitter has a low profile when attached to snakes (Fig. 1). Nominal battery life was 34 days, but many units exceeded this duration.

Initially, we used the method of Rathbun et al. (1993), which incorporated several strips of 3M™ Blenderm® clear plastic surgical tape. We also tried a type of cloth-backed gaff tape manufactured by Shurtape® that had been successfully used to mount transmitters onto penguins (C. Ribic, pers comm.). In 2004, we began using camouflage Duck® brand duct tape.

In addition to the various tape products we tried, we also modified the position of the transmitter on the snakes over the course of the study. Initially, we taped the antenna to the ventral surface of the snake and left the transmitter trailing off the end of the tail ("off-tail" method; Fig. 1), following Rathbun et al. (1993). In 2004, we changed the attachment site so that the transmitter was positioned on the ventral surface of the snake, about three-quarters of the distance from the snout to the vent, and the short antenna was directed caudally ("body" method; Fig. 2). We encircled the snake's body and the transmitter using one piece of tape (about 3 × 9 cm), which overlapped slightly on the dorsum of the snake. We secured the tape to the snake's ventral scutes anterior to the transmitter to prevent the transmitter's leading edge from snagging on obstacles in the environment. The reasoning for this ventral placement is that the radio transmitter would push into the body cavity by the weight of the snake thereby minimizing changes in the cross section of the snake as it moves through the environment. In removing transmitters from snakes, we carefully cut the tape with surgical scissors and cleaned any remaining adhesive on the skin with isopropyl alcohol.

We located snakes with transmitters 5–10 times per week from May through September, and 1–5 times per week thereafter until transmitters dropped off, were removed, or failed. Each time we located a snake, we attempted to confirm that the transmitter was still attached. We conservatively calculated retention time as the period from the snake's release to the last time the transmitter was known to be on the snake, either through visual contact or subsequent movement. Distances that individuals carried transmitters before dropping them were calculated as the sum of all movements from the release site to the final location. To determine if one attachment method or type of tape remained on snakes longer, we compared distances and durations by the type of tape and attachment technique. We used Kruskal-Wallis one-way analysis of variance to make these comparisons (JMP IN 5.1.2, SAS Institute, Inc., Cary, North Carolina, USA).

We attached radio transmitters to 62 *T. gigas* (39 females and 23 males) a total of 75 times in the course of three field seasons. Telemetered individuals averaged 76 cm (range: 60–98 cm) in snout-vent length and 271 g (range: 93–600 g) in mass.

For off-tail gaff tape attachment, snakes ranged from 69–72 cm and 138–600 g. For body gaff tape attachment, snakes ranged from 72–90 cm and 110–480 g. For body duct tape attachment, snakes ranged from 60–98 cm and 93–515 g.

TABLE 1. Summary statistics for different locations and materials for externally attaching radio transmitters to snakes. N = number of attachments.

				Duration (days)		Distance (m)	
Method	Tape	Year	N	Mean	Range	Mean	Range

body	duct	2004, 2006	22	22.9	0.2–88.0	440	35–1432

Results.—Nine individuals dropped their transmitters prior to the first relocation. The remaining 66 transmitter attachments remained on the snakes for a mean of 14.3 days (range: 0.16–88 days), and were carried a mean distance of 391 m (range: 20–1700 m). All functioning transmitters were eventually recovered.

Our first attachments using the off-tail method with surgical tape (N = 5) failed almost immediately because of lack of adhesion of this tape, and we obtained no usable data from these individuals. Individuals with transmitters attached using the off-tail method with gaff Shurtape® tape (N = 42) traveled a mean distance of 371 m and retained their transmitters for a mean of 11.1 days (Table 1): however, radios in the off-tail position became entrapped in the environment in 13 individuals. Using gaff tape and the body method (N = 6), we were able to track snakes for a mean of 5.9 days (Table 1). We discontinued use of gaff tape after we discovered that its adhesive qualities were diminished after storage during the winter. With duct tape on the body (N = 22), individuals traveled a mean of 440 m and kept their transmitters for a mean of 23 days (Table 1).

We found no statistical differences ($p > 0.10$) in distance travelled ($\chi^2 = 0.907$, $p = 0.341$, $df = 1$) or duration of transmitter retention between transmitter attachment site ($\chi^2 = 0.254$, $p = 0.614$, $df = 1$) or tape type ($\chi^2 = 2.003$, $p = 0.157$, $df = 1$). We found no evidence of entrapment problems with radios attached by the body method. We found no discernable relationship between snake size and duration of radio attachment ($r = 0.13$, $p > 0.15$).

We recaptured 21 snakes that had external transmitters 95 times after their first attachment. Our overall recapture rate at both study sites from 2003 through 2006 was 2.0 captures per snake. We noted five snakes with scarring resulting from the off-tail attachment technique and four snakes with scarring from attaching the transmitter to the body. Several snakes could have carried transmitters longer and farther than we were able to measure. We were unable to recover nine transmitters before the batteries discharged or otherwise malfunctioned. On four occasions we removed attached, functional transmitters from snakes at the end of the field season. The longest duration for snakes retaining taped radio transmitters was in the late summer to early winter of 2006: three snakes were marked with the body taping method using Duck® tape from late summer into early fall. These radios remained on one snake for 42 days, and 87 and 88 days for the other two snakes.

Discussion.—Other investigators have used various techniques to attach transmitters to various snake species with mixed success. Ciofi and Chelazzi (1991) passed rubber tubing beneath the 22nd and 27th subcaudal scales of *Coluber viridiflavus*, providing an anchor through which they attached transmitters with nylon thread, which facilitated replacement of batteries without removing transmitters. Gent and Spellerberg (1993) studied movement rates for short periods (mean = 4.7 days) in *Coronella austrica* by mounting small transmitters on the dorsal side of the tail with surgical tape. Of 50 attachments, five were dropped on the first day and seven became snagged on vegetation and were removed by the researchers. Rathbun et al. (1993) taped transmitters onto the tail of nine *Thamnophis hammondii* using several strips of surgical tape. *Thamnophis hammondii*, another semi-aquatic gartersnake, retained their transmitters for a mean of 24.2 days. Cobb et al. (2005) and Figueroa (2006) glued small transmitters onto neonate *Crotalus horridus* and *C. oreganus helleri*, respectively, using cyanoacrylate glue, as did Jellen and Kowalski (2007) for neonate *Sistrurus catenatus*, with transmitters lasting 13–56 days. Although we did not evaluate a gluing method, it may not work well on the thin, smooth-scaled skin of *T. gigas* compared to the thick, rough scales of rattlesnakes.

More recently, Tozetti and Martins (2007) and Madrid-Sotelo and Garcia-Aguayo (2008) used duct style tape to externally attach radio transmitters to *Crotalus durissus* and *Oxybelis aeneus*, respectively, with an average monitoring time of 69.2 and 48.3 days, respectively. These attachments were dorsal compared to our ventral method. Madrid-Sotelo and Garcia-Aguayo (2008) also used cyanoacrylate glue in addition to the tape to affix the radio transmitters. Our monitoring time and that of Tozetti and Martins (2007) shows that duct tape alone can provide sufficient adhesion of radio transmitters to snakes. Again, our work shows that tape sufficiently adheres to these smooth-scaled snakes as well as the rough-scaled snakes in the study by Tozetti and Martins (2007). Also our work shows that ventral attachment of radio transmitters can work successfully in wetland habitats.

By attaching transmitters externally, we were able to obtain movement data on those *T. gigas* that were smaller than implantation procedures permit. We were also able to increase our sample size for snakes of all sizes. In addition, we were able to attach transmitters in the field immediately following snake captures, thereby reducing the interruption caused by captivity, anesthesia and surgery. An externally

attached transmitter that fails prematurely will be lost by ecdysis, whereas implanted transmitters will remain in the body of the snake with unknown long-term consequences. During the active season, *T. gigas* shed their skin every 4–6 weeks, which invariably resulted in the loss of the transmitter. We found that *T. gigas* are often out of their burrows just prior to shedding, which permitted us to replace transmitters and continue tracking individuals.

We found the off-tail transmitter attachment technique was potentially more hazardous to the snakes than the body attachment. Four off-tail transmitters we recovered were snagged in vegetation, and the attached tape had distal pieces of tail that were pulled off by snakes. The shed radios we recovered that were attached with the body method showed no evidence of harming the snakes, but tape adhesive occasionally caused some superficial scarring. The small amount of tape used to affix transmitters with the body technique confers an additional advantage over the multiple pieces required to secure the antenna in the off-tail technique. When compared to the invasiveness of surgical implantation (Rudolph et al. 1998), the complications from taped transmitters are relatively minor. Taping did not cause any apparent mortality of the individuals in our study. The location of the radio attachment should be sufficiently posterior to allow for passage of gut contents at that location; we found no evidence of blockage of food items. We also did not detect any interference with shedding by taped radio transmitters.

We attribute our success of taping transmitters to *T. gigas* to several factors. The wetland habitat used by *T. gigas* has very little lignified vegetation and rocky outcroppings, and thus may be particularly forgiving to ventrally-mounted transmitters. Additionally, radio telemetry was conducted with concurrent, intensive snake trapping so we were able to recapture many animals, replace transmitters, and continue collecting data on the same individuals. A number of animals lost transmitters quickly and our dataset includes a long period of trial and error. In addition, our conservative calculations of distance and duration were designed to illustrate minimum expectations using our attachment method. Thus, our results may not reflect the full potential of this technique.

Taping radio transmitters to snakes is a simple, non-invasive and cost-effective way to collect movement data on individuals. This technique circumvents some of the limitations imposed by surgical implantation of transmitters, such as precluding studies of small snakes, poor recovery in cool weather (Rudolph et al 1998), and erratic behavior following periods of captivity while snakes recuperate from surgery. After surgically implanting transmitters in *T. gigas*, it is necessary to maintain them in captivity for up to two weeks to facilitate healing of the incision (Smith et al. 1988). Following this prolonged period of captivity, snakes often made unusually large movements immediately after release. Taping a transmitter to a newly captured snake and releasing it immediately rarely resulted in this response.

The period of time that a taped transmitter remains on a snake is not conducive to examine seasonal patterns in movement or annual home ranges. However, external transmitter attachment may facilitate research goals requiring one to monitor snake behavior over a within-season period (e.g., to measure rates of movement, Gent and Spellerberg 1993), or to monitor neonatal dispersal (Cobb et al. 2005; Figueroa 2006), reproductive behavior, habitat use, dispersal from hibernacula, and responses to landscape edges or features such as roads. The use of tape to attach radios in the fall facilitated location of winter hibernacula. Additionally, basking behavior associated with ecdysis facilitated transmitter replacement and continued long-term monitoring of individuals in spring and summer. Thus, our taping technique for the external attachment of radio transmitters to snakes, in addition to the variations tried by Tozetti and Martins (2007) and Madrid-Sotelo and Garcia-Aguayo (2008), demonstrates the potential for diverse applications of this technique in snake ecology and conservation. We recommend the use and further evaluation of the duct tape "body" method for use in future studies of snake movements.

Acknowledgments.—We thank Galen Rathbun for showing us his taping technique and helping us start this study. We also thank the many field technicians who participated in this study. B. J. Halstead and E. M. Nowak provided helpful reviews of earlier drafts of this manuscript. Snakes were handled in accordance with the University of California, Davis, Animal Care and Use Protocol 9699 and as stipulated in our U.S. Fish and Wildlife Service Recovery Permit TE-020548-5.

Shell Hardness Measurement in Juvenile Desert Tortoises, *Gopherus agassizii*

Thick, hard shells of adult tortoises and many turtles confer protection from predators and have apparently evolved among chelonians largely in response to predation pressures (Wilbur and Morin 1988). When threatened, turtles and tortoises pull in their heads and limbs, tuck in their tails, and present an armored surface and relatively round, smooth shape to their attackers—a defense that is usually successful in deterring injury or death from most predators (but see Emmons 1989; Medica and Greger 2009). However, hatchlings and young juveniles of many species have very soft, un-ossified shells and may suffer high mortality from predation (Ashton and Ashton 2008; Gilbert et al. 2008; Van Devender 2002). The rate at which shells harden (ossify) apparently has not been studied, but such information is important, especially in conservation efforts. For example, field studies of the threatened Desert Tortoise (*Gopherus agassizii*) have revealed very high predation pressures on young, mainly from ravens (Boarman 2003; K. A. Nagy, L. S. Hillard, S. Dickson, and D. J. Morafka, unpubl. data).

Chelonian species recovery programs involving head-starting procedures, which protect nests, hatchlings, and juveniles from predation until the young animals have grown through the highly-vulnerable stages, will involve decisions about when to release the juveniles into the wild. Such decisions should benefit from information regarding rates of development of shell hardness and shell size. Paired with data on predation and survivorship, knowledge of shell hardness would allow researchers to more fully understand how shell hardness influences predation risk and survivorship and identify particularly vulnerable periods in the life of juvenile chelonians. This information would allow for the development of better-informed conservation and management decisions. Also, knowledge of rates of shell hardening and shell growth can contribute to basic understanding of shell ontogeny among chelonians, as well as help answer ecological questions about effects of variability in average annual temperatures and rainfall, invasive species, and competition for food by other species on shell growth rate and ossification.

Finally, comparisons of juvenile shell hardness development between populations or species may elucidate patterns of life-history evolution in response to differential predation patterns. Accordingly, we developed a reliable method for measuring shell "hardness" (compressibility) using machinist's calipers and applied it in a preliminary study of juvenile desert tortoises living and growing under essentially natural conditions in fenced enclosures in the open desert to predict the age and size at full shell hardening.

MATERIALS AND METHODS

Instrumentation.—Shell compressibility was measured using a 4-inch (maximum gap size), tension-calibrated, digital micrometer (Aerospace® brand; Fig. 1). The micrometer had a measurement range (spindle "throw") of only one inch, but we used 1-, 2-, and 3-inch inserts to allow measurement of shells ranging from zero to 102 mm (4 in) in height. The inserts were actually the calibration standards that came with the set of four micrometers (having jaw sizes of 1-, 2-, 3-, and 4-inches). Preliminary tests indicated that each of the four micrometers had rather different factory-set release tensions. Accordingly, we used only the largest micrometer, so as to minimize instrument error across various sizes of tortoises, adapting it to accommodate tortoises smaller than 75–100 mm by using the inserts. We fitted each of the three calibration standards with its own machined plastic collar

FIG. 1. Micrometer (4-inch), fitted with the 3-inch insert and machined white plastic collar to hold the insert in place, and shown attached to the wooden stand that was used for support in the field. This configuration allowed measurement of shell heights of up to 25 mm (one inch). Shell heights between 25–100 mm (1–4 in) could be measured by using either of the two shorter inserts (for 25–50 mm or 50–75 mm shells) or no insert (75–100 mm shells).

with set-screw so it could be attached and secured flush with the lower cylindrical measuring face of the micrometer. The micrometer was attached to a wooden stand to enable hands-free use (Fig. 1). The small knurled knob ("thimble") on the end of the handle advanced the spindle via a tensioned ratchet. When the spindle applied a factory-set force to the object being measured, the ratchet slipped, producing clicks, and the spindle no longer advanced.

The force exerted by the spindle at the pressure point where the ratchet slipped continuously averaged 636 g (SD = 37, CV = 5.8%, N = 7). The surface area of each measurement face was 28.3 mm^2, thus the force being exerted by both micrometer faces combined on the shell of tortoises when measuring CSH was 11.2 g/mm^2. No tortoises or shells showed any damage from our measurements. We purposely did not make measurements on hatchling tortoises due to their very thin and rubbery shells.

Measurement technique.—To measure shell heights, we held a tortoise level in its normal horizontal posture, then positioned the tortoise in the micrometer at its maximum shell height point, with its plastron just touching the lower caliper spindle face, or insert face, as appropriate for the size of the tortoise. We then determined the uncompressed shell height (USH) by slowly lowering the upper spindle by turning either the large knurled cylinder or the small knurled knob until the upper measuring face just touched the carapace, while being careful not to press the tortoise's plastron down on the lower measuring face and not to allow the tortoise to rest on the lower measuring face so its body weight deformed its plastron. We confirmed this "loose fit" in the caliper by very slightly sliding the tortoise back and forth, to assure that both caliper measuring faces were barely touching the tortoise's shell. The micrometer reading was recorded as USH, then the compressed shell height (CSH) was determined by continuing to rotate the small knob until the ratchet slipped continuously and at least six ratchet clicks in a row occurred. We recorded the micrometer reading at that point as the compressed shell height (CSH) value. It was important to make the CSH measurement gently but quickly, for two reasons. Small tortoises, which had the most compressible shells, sometimes began moving their legs after a short period of being compressed, adding uncertainty to the CSH measurements. Second, the shells of smaller tortoises were sufficiently elastic that if a tortoise was allowed to remain in the calipers at the compressed height position for another 10 or so seconds, it was then possible to compress them further before the six-click tension was again reached.

Hardness calculation.—Shell Hardness Index (SHI) was calculated with the equation:

$$SHI = 100\ (CSH/USH)$$

where CSH is compressed shell height and USH is uncompressed shell height. Both heights in this study were measured to ± 0.001 inches.

SHI Reproducibility.—We evaluated the "machine" repeatability of the USH, CSH, and SHI determinations by making repeated measurements of USH and CSH on a flexible "tortoise mimic," which was a rubber pipette bulb. To evaluate "animal" repeatability, we made duplicate measurements of SHI on four yearling tortoises. We only made two measurements per animal because their soft shells were slow to recover their original shape following a SHI determination. We allowed 30 min between duplicate measurements to allow for shell recovery. The force exerted by the spindle at the pressure point where the ratchet slipped continuously was measured by inserting a small portable balance into the micrometer in place of a tortoise.

Field measurements.—We made initial applications of this method on two populations of Desert Tortoises (*Gopherus agassizii*) living in the field. Juvenile tortoises were studied at the Fort Irwin head-start facility (described in Morafka

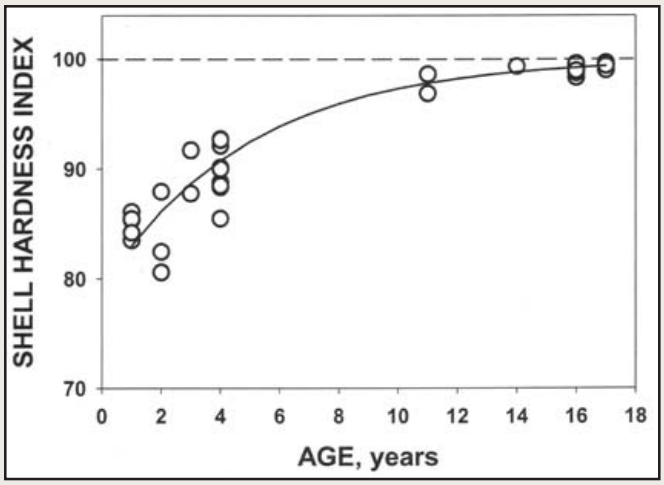

FIG. 2. Relationship between shell hardness and the age of juvenile tortoises living under natural conditions in the Mojave Desert. The solid line is an asymptotic curve fitted to the data, and the dashed line indicates a fully rigid shell, as in adult tortoises.

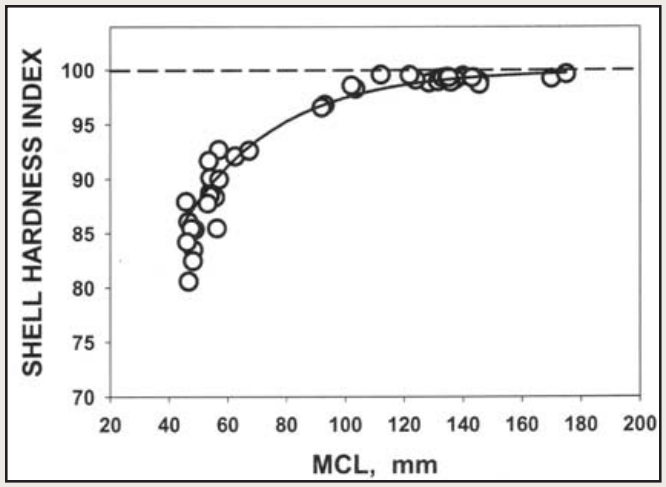

FIG. 3. Relationship between shell hardness and shell size (midline carapace length) of juvenile tortoises. The solid line is an asymptotic curve fitted to the data, and the dashed line indicates a fully rigid shell, as in adult tortoises.

et al. 1997 and Nagy et al. 1997), near the southern boundary of the US Army's National Training Center (35.1333°N, 116.4833°W) and at the Edwards Air Force Base head-start facility (34.7833°N, 117.7833°W) during 2007. The 28 tortoises studied at Fort Irwin were hatched inside predator-resistant, natural habitat enclosures between 1991 and 2003 and lived there under essentially natural conditions until their release into nearby open habitat in 2005 and 2006. They have been radio-tracked regularly since release. During recaptures in 2007 we measured SHI and midline (straight-line) carapace lengths (MCL in mm, measured from the notch just above the head to the notch above the tail to the nearest 0.1 mm with either digital or dial stainless steel 6-inch calipers). The 13 juveniles at Edwards AFB were also hatched inside fenced enclosures in natural habitat and their enclosures received only natural rainfall. They ranged in age from 1 to 4 years old when studied and we measured their MCLs and SHIs also during 2007.

Statistics.—We analyzed the relationships between SHI and tortoise age or MCL graphically, using SigmaPlot® (9.0) software. For regression analyses, we converted SHI values to shell compressibility values by subtracting SHI values from 100 so that "shell compressibility index" asymptotically approached zero as either age or MCL increased. The semi-logarithmic plots of these data yielded linear relationships, which we subjected to least-squares linear regression analyses with SigmaStat® (3.1) software. We used $\alpha = 0.05$ in tests for significant differences of the slopes and intercepts from zero.

RESULTS

Measurement reproducibility.—"Machine" repeatability measurements indicated that for USH the coefficient of variation (CV = 100 [SD/mean]) for 6 measurements was 0.15 %. For CSH, the CV was 1.32 % and for the SHI the CV was 1.35 %. "Animal" repeatability measurements indicated that the differences between duplicate SHI estimates were <4 % of the average measured SHI values of the four juveniles.

Field application results.—The shells of the 41 juvenile Desert Tortoises we measured had SHI values ranging from 80 to 100 (where SHI = 100 represents an incompressible shell). Among 39 juveniles for whom we had reliable age estimates, shells became harder in an apparently asymptotic manner as age increased (Fig. 2). There was more variation in shell hardness within younger cohorts than in older cohorts. The relationship between SHI and shell length, for 41 animals in this case, was also apparently asymptotic (Fig. 3). The relatively high variation in SHI among the smaller juveniles was again evident.

Predicting age and size at full shell hardening.—The relationship between SHI and age was significant ($F_{1,37} = 635.78$, $P < 0.001$, $R^2 = 0.945$) and gave an equation of ln(100-SHI) = 3.036-(0.203*AGE). Similarly, the relationship between SHI and size was significant ($F_{1,39} = 406.14$, $P < 0.001$, $R^2 = 0.912$) and gave an equation of ln(100-SHI) = 4.036-(0.031*MCL). If solved for an assumed SHI value of 98% of full shell hardness, predicted age is 11.5 years and predicted shell length is 109 mm. If the equations are solved with an assumed SHI value of 99%, predicted age is 15 years and predicted length is 130 mm MCL.

DISCUSSION

Shell hardness of young Desert Tortoises can be successfully and harmlessly evaluated using measurements of shell dimensions made with a micrometer equipped with a tension-developing ratchet-release thimble. A 4-inch micrometer along with 1-, 2-, and 3-inch spacer inserts allows a single micrometer to be used on tortoises ranging in shell height from yearlings <25 mm high up to 100 mm high. The advantage of using a single micrometer is that its unique ratchet

release force should be the same for all animals measured, thus reducing error. The micrometer we used came from a set of four that ranged in size from 1 to 4 inches. Tests on the other three micrometers indicated that each had its own unique ratchet release force and all were precise but the mean forces developed differed by as much as 33% between micrometers. Thus, using a single micrometer can reduce measurement error substantially. Measurements of compressed shell height (CSH) were an order of magnitude more variable than those for uncompressed SH (CVs of 0.15 % and 1.32 %, respectively, for the rubber bulb "tortoise mimic") because of the added variability of the ratchet's slipping point and variation in the exact position and orientation of the compressed rubber bulb in the micrometer jaws. Nevertheless, the reproducibility (precision) of the shell hardness index (SHI) measurements was good (<2% CV for the rubber bulb and about 4% CV for living year-old tortoises). By using an "Index" rather than actual dimensions for shell hardness, results for tortoises of different sizes and ages can be compared directly.

Shells of neonate Desert Tortoises were quite soft during the months following hatching, with shells being compressible by more than 40% under moderate pressure. Because of the apparent discomfort some neonates showed and because of the possible injury to their very soft and thin shells, we did not make formal SHI determinations on neonates. Instead, we waited until the following spring, when neonates were about 7 months old, to begin measurements. At this age, SHI values were quite variable but averaged about 85% of full hardness. Over the next several years of life, shells hardened in an asymptotic fashion, and the log-transformed regressions of shell hardness with both age and shell size were linear. The high R^2 values for these relationships suggest that age and shell length account for most of the variation in log shell hardness in juvenile desert tortoises. Their shells became essentially incompressible (within 2% of complete shell inflexibility under a moderate force of 11.2 g/mm^2) by the age of about 11 years and a size of about 110 mm MCL.

These results can be useful in current tortoise conservation efforts. The Mojave Desert populations of *Gopherus agassizii* suffered severe declines in the 1970s and 1980s and were listed as Threatened in 1990 under the Endangered Species Act. The Recovery Plan (U.S. Fish and Wildlife Service 1994) included increased predation, particularly on hatchlings and juveniles, as a reason for listing. Natural mortality of the young of several species in the genus *Gopherus* is known to be quite high (Germano 1994; Morafka 1994; Tom 1994; Wilson et al. 1994; but see Bjurlin and Bissonette 2004). Hatchlings and young juveniles are small and have soft shells that make them much more vulnerable to predation than the hard-shelled and relatively large adults (Bjurlin and Bissonette 2004). The soft shells of juveniles may also be involved in their more rapid loss of body water and increased susceptibility to dehydration during droughts as compared to adults (Nagy et al. 1997). Several head-start projects are now underway in the Mojave Desert to protect tortoise nests, eggs, and juveniles from predators until they can be released with an expectation of high survivorship. We recommend that such tortoises be maintained under protection of the head-start pens until they reach a shell hardness of at least 98%. Tortoises in our sample, which were receiving natural rainfall and eating natural vegetation, reached this hardness by about 11 years of age or about 110 mm midline carapace length.

Shell hardness likely confers resistance to predation. Knowledge of the rates of development of shell hardness, paired with information regarding local predator populations and predation rates on juveniles with differing shell size or hardness, would allow managers of head-start programs to make informed decisions regarding the timing of the release of captive-raised juveniles based upon shell size and hardness. For example, understanding the relationship of juvenile desert tortoise shell size and hardness to predation risk by common ravens would allow managers to make decisions that maximize survivorship rates of released juveniles in areas with high raven densities. Additionally, knowledge of the effects of experimentally varying the growing conditions within head-start pens may provide information (1) to evolutionary biologists examining environmental influences on life-history evolution, (2) to population ecologists developing life tables for population modeling and conservation plan development, and (3) to managers maximizing the productivity of a head-start program using rearing techniques that enhance shell growth or hardness. For example, knowledge of differences in shell growth and hardness for juveniles raised in areas or in pens having differing proximate climates, watering/precipitation regimes, annual or seasonal food abundance or quality, or competition from other herbivorous species or pen mates (crowding effects) would reveal the importance of these ecological influences on juvenile tortoise ontogeny and life-history evolution.

The ability to determine degree of shell hardness or compressibility may be useful in studies of the ontogeny of shell growth and ossification in a variety of tortoise and turtle species. From an evolutionary perspective, comparisons of the development and growth of juvenile tortoise shells and their effects on reducing predation risk or enhancing survivorship among different populations or between species can be instructive in determining the effect of predation on life-history evolution. For example, researchers could examine whether juvenile tortoises in environments with lower predation risk allocate more energy toward shell growth at the expense of shell hardness, thereby growing and maturing faster than juveniles in populations or species located in areas of higher predation risk.

Rediscovery of *Abronia frosti* (Sauria: Anguidae) from a Cloud Forest in Cuchumatanes Highlands in Northwestern Guatemala: Habitat Characterization and Conservation Status

Species of *Abronia* are known to occur from southern Tamaulipas and Guerrero, Mexico, to southern Honduras. Guatemala has been a center of diversification of this group, with 10 species, eight of which are endemic (Ariano-Sánchez and Melendez 2009; Campbell and Frost 1993). A number of species of *Abronia* are critically endangered in the wild and two species (*A. campbelli* and *A. frosti*) were thought to have become extinct shortly after their discovery (Acevedo 2006; Acevedo et al. 2010; Brodie and Savage 1993; Campbell and Brodie 1999; Campbell and Mendelson 1998; Campbell et al. 1998). These two species had not been recorded in Guatemala since the late 1990s. Recently, however, a remnant population of *A. campbelli* was discovered in the country (Ariano-Sánchez and Torres-Almazán 2010). Acevedo et al. (2010) reported that three trips to the type locality between 1997 and 1999 failed to find any individuals of *A. frosti*. These authors also reported that the entire habitat in the area had been burned and that the species was presumed extinct. The rediscovery of *A. frosti* in this report was a result of a project focused on research and conservation of the Guatemalan species of *Abronia*. This project began in June 2009 and is operated by the Guatemalan NGO Zootropic.

Materials and methods.—Beginning in October 2009, a number of trips were made to the type locality of *A. frosti* (Campbell et al. 1998), in the northwestern part of Sierra de los Cuchumatanes, Guatemala, to search for the species. Standardized interviews with local villagers were conducted to determine the presence of *A. frosti* within the area. Interviews included showing local inhabitants photographs of *A. frosti* taken from Campbell et al. (1998), as well as images of the locally common species *Mesaspis moreletti* and *Sceloporus taeniocnemis* that are reasonably similar in appearance to *Abronia*. In addition, visual searches for the species were made in suitable habitat (including climbing oak trees) in the region.

Results.—Answers to standardized interview questions during the early trips to the area determined that local villagers were able to distinguish *A. frosti* from the other species of lizards in the area. In addition, villagers reported still seeing this species locally when they cut down old oak trees for firewood and within fresh masses of moss recently fallen from high tree branches after storms. Standardized interviews also revealed that the local inhabitants used to kill the lizards, until recently, because of a belief that seeing these animals is a bad omen; the very recent reduction in the killing of lizards by the local villagers is likely due to a very effective education program initiated in the area by our group.

The cloud forest inhabited by *A. frosti* is composed mainly of two species of oak: *Quercus boruscana* and *Q. acatenangensis* (Fig. 1). The trees of this forest are heavily covered by thick masses of moss and epiphytes and have an average height of 45.5 ± 4.26 m and an average diameter at breast height of 178.15 ± 19.83 cm. During our survey visits we found that the cloud forests in the region had been severely degraded due mainly to harvesting of the original oak forests for firewood (Fig. 2).

A sub-adult specimen of *A. frosti* with a SVL of 70 mm was found in October 2010 resting on a recently cut oak tree within a cloud forest remnant near the type locality in the highlands of Sierra de los Cuchumatanes, Huehuetenango, Guatemala (Fig. 3). The specimen was captured for the initiation of a captive breeding survival assurance colony, as part of the short-term conservation program for this species.

Discussion.—*Abronia frosti* has not been documented in the wild since its original discovery, 12 years ago, despite specific efforts to do so by different groups of herpetologists

COLOR REPRODUCTION SUPPORTED BY THE THOMAS BEAUVAIS FUND

(Acevedo et al. 2010). One of the main factors for the success reported in this paper was the participation and support of local villagers within the area. This cooperation by local inhabitants was due to an awareness campaign conducted by Zootropic. Educational workshops with villagers were conducted in the Cuchumatanes region in order to increase the public awareness about the importance of the conservation of the cloud forest this species inhabits. Cloud forest in the area is severely fragmented, consisting mainly of small patches of intact habitat surrounded by a matrix of deforested land and plantations of native pine trees. In contradiction to Acevedo et al. (2010), the survey in this report finds that despite the degradation and fragmentation of the habitat, there remain some oak forest remnants within the area that should be considered for protection.

The height and diameter of the trees where *A. frosti* is found (Campbell et al. 1998; this report) suggest that this species is probably restricted to mature cloud forest habitat. The main factor leading to the decline of cloud forests in this region is logging for the production of firewood for both local use and commercial sale in the regional population center of San Mateo Ixtatán. Main conservation actions for the species should focus on preserving the last cloud forest remnants within the area and also the initiation of a captive breeding survival assurance colony of the species.

The rediscovery of *A. frosti* reported here and the recent rediscovery of breeding populations of *A. campbelli* in small forest remnants (Ariano-Sánchez and Torres-Almazán 2010) provide hope that these species may be somewhat resilient to the effects of forest fragmentation and habitat destruction. The discovery of a sub-adult *A. frosti* may mean that a breeding population of animals persists in the area lending further evidence to the persistence of this species in the midst of habitat degradation. Although the resilience of *A. frosti* to extinction is encouraging, there are a number of critical steps that need to be taken to ensure the long-term survival of this species in the region: 1) increase the connectivity within remaining, intact forest patches; 2) preserve the remaining cloud forest remnants; 3) reduce or eliminate the taking of individuals (killing and collection for illegal trade) by local villagers; and 4) promote the restoration of critical oak forest habitat.

The implementation of the above-proposed conservation measures may be difficult to accomplish due in great part to the complicated system of land use in the region. The majority of the forest range of *A. frosti* is managed as communal property. The residents of this region are not in agreement on the best use of this forest, including any reforestation program. In order to preserve the last remaining stands of mature oak forest in the area it will be critical to develop a program, along with the San Mateo Ixtatán municipality, to decrease logging for firewood in the area. One consideration in this area would be to increase the efficiency of ovens and kitchens of local villagers. Another strategy would be the promotion of establishment of plantations of fast growing tree species, suitable for firewood, in deforested areas near towns

as an alternative to oak forest harvest. Another option is to promote the conservation of the last forest remnants through the formal participation of these communal properties within the Guatemalan system of protected areas. This strategy would require a strong political effort by the leaders of the communities that own the land. For these political leaders to promote these conservation actions will require the implementation of an effective and sustained program for the conservation of the last cloud forest remnants in northwestern Sierra de los Cuchumatanes.

Acknowledgments.—We thank two anonymous reviewers for comments that have improved this paper. This work has been possible though funding by Zootropic, Zoo Atlanta, Zoological Society for the Conservation of Species and Populations (ZGAP), Mohamed Bin Zayed Fund (MBZ), Microsoft Corporation Fund (via Jason Wagner), Humane Society International, and International Reptile Conservation Foundation. We thank Thomas Schrei for the amazing photographs he has taken of the specimen reported here. Special thanks to Luis Alvarado, Brad Lock, and Lester Melendez for their support and for providing valuable suggestions for the project since its inception. We thank all the local villagers who provided help within the area. Cesar Castañeda helped in the identification of the tree species in the area. CONAP provided the legal permits for conducting this research according to permit No. 050/2009.

Note added in proof: In May 2011 another specimen of *Abronia frosti* (SVL 79.62 mm) was found by a local villager near the type locality. This individual is probably a female and was captured for the captive breeding program at Zootropic.

Prime Time for Turtle Conservation

In the race to extinction among all large groups of well-known animals, turtles hold the lead with 47.6% of 320 currently recognized turtle species identified as "Threatened" with extinction (Turtle Taxonomy Working Group [TTWG] 2010). Hoffmann et al. (2010) calculated threat levels a bit differently, by excluding data deficient or unevaluated species from the calculation; this method yields a higher percent of Threatened turtles, 54%. This exceeds global threat estimates for amphibians (41%), mammals (25%), bony fishes (15%), and birds (13%), and is similar only to primates, with 48% Threatened (Hoffmann et al. 2010). Furthermore, if our view is expanded to include 'modern' turtles and tortoises, those species that have occurred in the last 400 years, then 50% are threatened or already extinct (TTWG 2010). This percentage increases to 57% if data deficient and unevaluated species are eliminated from the calculation. By any of these approaches, turtles are in dire straits.

Partners in Amphibian and Reptile Conservation (PARC) is working with turtle and tortoise conservation groups to raise awareness for turtles by designating the year 2011 as the 'Year of the Turtle.' Their hopes are to: 1) communicate the need for conservation, research and education to the public, nature enthusiasts, biologists, and managers; 2) showcase ongoing work and species concerns; 3) acquire critical new

COLOR REPRODUCTION SUPPORTED BY THE THOMAS BEAUVAIS FUND

information for selected species; 4) look for opportunities to leverage across diverse efforts to enhance effectiveness of actions; and 5) work to develop new procedures and policies that will benefit chelonians. Their website (www.yearoftheturtle.org) features monthly newsletters, calendar pages, partner links, and selected project information. Modeled, in part, after the highly successful 2008 – Year of the Frog that was organized by the Association of Zoos and Aquariums, the 2011–Year of the Turtle is a mechanism to network among those doing turtle and tortoise work, and those private citizens, groups or specialists that are interested in their plight.

Although Year of the Turtle is gaining worldwide momentum, it has a particular focus on chelonians in North America, where PARC has a growing constituency. Also, among world nations, the United States is a turtle and tortoise biodiversity hotspot. There is heightened concern to preserve the unique natural heritage of turtles in this geographic area. Currently, 57 of the 320 (18%) species of turtles known worldwide occur in the United States, with Mexico being the second-most turtle-rich nation, having 46 species (TTWG 2010). Furthermore, these two North American nations rank highest in turtle species diversity if the counts exclude sea turtles, with USA having 51 species (81 species and subspecies) and Mexico having 40 species (58 species and subspecies) (TTWG 2010). Twelve species of freshwater turtles and tortoises occur in Canada. Retaining the North American turtle natural heritage is a specific conservation concern. Here, we offer a primer on the status of world turtles, with some specific information and conservation and research recommendations for the North American fauna.

TURTLE STATUS AND THREATS

The conservation status of world turtles and tortoises is currently under reassessment. The International Union for the Conservation of Nature (IUCN) Red List is the official list of the conservation status of turtles and tortoises. An update to the list will be released this year, 2011, with scores of new species evaluations to be added. The current Red List, version 2010.4, includes 207 species (Table 1). Draft Red List designations for re-evaluated and newly evaluated turtles were released in December 2010, showing a raise in species in Threatened categories, from 129 to 152 (shaded rows, Table 1). The Convention on Trade in Endangered Species (CITES) species lists address international trade guidance. International law is enforced by countries that are party to this treaty; nearly all countries are signatories. CITES classifies species into three Appendices that are grades of protection. These Appendices are due for revision in 2012, and draft revisions to turtle and tortoise listings are being made now. Currently, there are 21 species of freshwater turtles and tortoises, as well as all sea turtles, on Appendix I, the most endangered group. CITES prohibits international trade for these species, except when the purpose of import/export is not commercial (e.g., scientific research). There are 23 species, seven genera, and one family (tortoises: Testudinidae)

FIG. 3. Bog Turtle (*Glyptemys muhlenbergii*).

on Appendix II, the list that identifies species that may become threatened unless trade is closely controlled. There are 18 species and one genus (*Graptemys*) on Appendix III, the list that identifies species of concern by a Party (country) that already regulates trade in the species and needs cooperation of other countries to prevent unsustainable exploitation. Permits or certificates are needed for international trade of these species. One USA species is on Appendix III.

North American turtle conservation concerns can be further assessed by their national status ranks. In the USA, 9 of 57 (16%) freshwater turtle and tortoise species are listed under the Endangered Species Act (ESA, Table 2). In Canada, 6 of 12 species have conservation status by the Committee on Status of Endangered Wildlife in Canada (COSEWIC, Table 3). These lists do not overlap. It should be noted that the COSEWIC species appear on species of concern lists for certain US States.

The two top threats to turtles worldwide and in the US and Canada are habitat loss and fragmentation, and overexploitation for food, traditional medicines, and pets. Exacerbating these threats is the basic life history of most turtles and the small total ranges of many species. Their low fecundity and the several years it takes for young turtles to achieve maturity result in populations that are not resilient to sudden losses (Congdon et al. 1993). Small ranges mean that there are fewer total individuals and that there are fewer options for conservation action. All Canadian turtles are at the northern extent of their range, attributing to concern status for half of them.

Some examples of US turtles in peril and the reasons for concern are given below. Many more could be given. Each case is an example of the general issues, but the details are always different and they do matter.

The Plymouth Red-bellied Turtle (once recognized as the subspecies *Pseudemys rubriventris bangsi* and now understood as a highly isolated population) is confined to approximately 17 ponds entirely within Plymouth County, Massachusetts, more than 400 km from the mid-Atlantic populations of the same species. Similarly, the Alabama Red-bellied Turtle (*Pseudemys alabamensis*) occurs only in parts of Mobile Bay drainage in Baldwin and Mobile counties in Alabama, and Harrison and Jackson counties in Mississippi. Other species have specific habitat requirements so that the total amount of real estate available to them is small. The threatened Bog Turtle (*Glyptemys muhlenbergii*) requires very specific, nearly pristine, bogs to thrive so that although it ranges from upstate New York to Georgia, there is too little habitat left. The Flattened Musk Turtle (*Sternotherus depressus*) occurs only within the Black Warrior River system of Alabama, but cannot now live in much of that river because of water pollution and increased human activities.

A group of special interest is the map turtles of the Gulf South. Here, eight species are restricted to one or a small number of associated drainages in the southern USA that lead to the Gulf of Mexico. For example, the Pascagoula Map Turtle (*Graptemys gibbonsi*) is restricted to the Pascagoula River drainage in Mississippi and the newly described Pearl River Map Turtle (*Graptemys pearlensis*) is confined to the Pearl River drainage only in Mississippi and bordering Louisiana. Because each of these species is only found in riverine habitat the total amount of area occupied is necessarily quite small. Scientists are currently preparing a new Red List assessment of these species and it is likely that many of them will be found to be vulnerable or endangered.

Two of three species of US tortoises, the Gopher Tortoise (*Gopherus polyphemus*) and the Desert Tortoise (*Gopherus agassizii*), are threatened by the enormous expansion of urbanization within their ranges. In Florida, the primary home of the Gopher Tortoise, development has been displacing tortoises at an alarming rate as that state has had one of the highest human population growth rates in the country. Similarly, much of the western portion of the Mojave Desert in California has seen most of the available land put to human use in the last two decades. For example, in Victorville, California, the human population grew from 64,000 in 2000 to approximately 112,000 in 2010. Unfortunately, Desert Tortoises have also been severely affected by disease outbreaks even in relatively remote areas (USFWS 2006).

Other turtles that have in the past been both widespread and common are now suffering from habitat fragmentation and the effects of roads. This creates a pattern of many small populations that cannot interact with each other. As road density increases, many scientists believe that a tipping point will be reached where many of the small populations will go extinct. The concern has been raised for the Common Box Turtle (*Terrapene carolina*), a mostly terrestrial species (Dodd and Franz 1993). So, even species that were formerly regarded as common may be prone to widespread decline.

Exploitation of turtles for Asian commercial markets has skyrocketed and is now a major conservation concern worldwide, including in North America (Turtle Conservation Coalition 2011). Turtles have played an important role in Chinese civilization at least since the Bronze-Age Shang Dynasty over 3,000 years ago. At that time, hundreds of thousands of turtles were used in divination rituals in which tortoise and turtle shells were heated and the cracks obtained were interpreted for guidance. These oracle bones fill archaeological sites. Turtles also have always been recognized for their longevity and the Chinese have sought to acquire that virtue from them. Today, turtles are consumed in China for long life and for traditional medicine. The problem, known as the Asian Turtle Crisis (van Dijk et al. 2000), arises from the combination of this long tradition with a population of over 1 billion people who are becoming wealthier. The demand for turtles in China is now almost impossible to overestimate. But the result is clear: turtles are being sent from all over the world to China for consumption at a scale unimaginable only a few years ago (Compton 2000; Chen et al 2009). Southeast Asian countries such as Vietnam now have their entire turtle fauna (over 30 species) critically endangered due to this trade (Hendrie 2000). The economic incentives for local peoples to

participate in this global trade are staggering. Any turtle is worth serious money to a Vietnamese peasant, but some species, such as the Three-striped Box Turtle (*Cuora trifasciata*), sell for several thousand dollars apiece (Blanck et al. 2006). They are literally worth their weight in gold.

Commercial markets for turtles include the pet trade. Around the world people keep pet turtles and tortoises. In the last few decades they have become much more popular and, most importantly, the number of species found in the pet trade has increased dramatically (Shepherd and Nijman 2007; Shepherd and Nijman 2008). While most pet owners have relatively common species and do not pose a major conservation threat, some collectors become fanatic about getting rare or unusual species. Today, almost every species of turtle can be found for sale, legally or not, on the internet. Fanatic collectors can buy the world's rarest turtles if they have enough money, and many do. Prices for adult Ploughshare Tortoises (*Astrochelys yniphora*) from Madagascar can range to well over US $10,000 (Smith 2011). This market has driven many species to near extinction (Turtle Conservation Coalition 2011). Especially frustrating to turtle biologists is that when a new, rare species is described in the scientific literature, this publication immediately creates a market for the new turtle (Stuart et al. 2006). For example, the Roti Island Snake-necked Turtle (*Chelodina mccordi*) was described from a single small island in Indonesia and within a very few years most of the population had disappeared into the international trade.

Several US states have tightened their regulations over the commercial exploitation of any turtle species (P. Nanjappa, pers. comm.), in part because of increased evidence for the growing demand for turtles in Asia and worldwide. Turtles are still captured for the pet trade but it is hard to know how much of a conservation concern this harvest is. Formerly, both Common Box Turtles (*Terrapene carolina*) and Ornate Box Turtles (*Terrapene ornata*) were sent to Europe in large, unsustainable numbers. But this trade has been much reduced after the genus was put on CITES Appendix II. The individual state laws governing collection of turtles in general are a patchwork with most states allowing collection for personal use

and others not. State herpetofaunal regulations have been compiled recently to aid in management of these animals (P. Nanjappa, unpubl. data). Unfortunately, much of the trade in rare species is illegal and therefore very hard to track, and few states have the capacity to establish effective monitoring programs.

An emerging threat for turtles is hybridization and genetic swamping. A major discovery in the biology of turtles became apparent recently when it was determined that almost any species of Old World freshwater turtle (Family Geoemydidae) could hybridize with any other species even if they were in different genera. More startling is that these hybrid offspring are fertile and capable of reproduction. Turtle farms in China have now produced turtles descended from three different genera between their parents and grandparents (T. Blanck, pers. comm.). These turtles are like orchids - endless new varieties can be produced. Hybrids have no legal protection under international law so a hybrid of two of the rarest turtles in the world is legal anywhere. These hybrid turtles show that habitat alteration that permits species that do not normally encounter each other to mix could cause a distinctive form to be lost through genetic swamping. Similarly, although this has not happened yet as far as we are aware, releasing hybrid turtles could cause the loss of native species. This threat is new and there is no other group of animals that faces a similar problem. We really have no idea how dangerous it could be. In the US, the chief concern is the introduction of the Red-eared Slider (*Trachemys scripta elegans*) into habitats of its close relatives, such as the Big Bend Slider (*Trachemys gaigeae*) which occurs in the Rio Grande drainage of Texas and New Mexico. This hybridization has the potential to wipe out the Big Bend Slider as a distinct species (T. J. Papenfuss, pers. comm.).

CALL TO ACTION: CONSERVATION AND RESEARCH RECOMMENDATIONS

Hoffmann et al. (2010) demonstrated that conservation actions can improve species status. We have the opportunity to change the fate of turtles around the world by taking steps implementing conservation actions, and doing so quickly. Let us use the Year of the Turtle as our Call to Action – we can work together to benefit turtles worldwide. The Partners page at the Year of the Turtle website (www.yearoftheturtle.org) lists some organizations that work on turtle and tortoise conservation, and many more groups and individuals are working to benefit these animals. Join one or start a new one. A source to learn more about the challenges and opportunities is Craig Stanford's *The Last Tortoise* (Stanford 2010). The most endangered species are reviewed by the Turtle Conservation Coalition (2011).

An important lesson that has emerged from consideration of the difficulties of turtle conservation is that all possible conservation tools must be considered and that each species and country have their own opportunities and challenges. This lesson leads to an overall ecumenical approach in which the effective use of any one conservation tool does not preclude the use of another tool. Sometimes there are conflicts between strategies, such as when trade regulations are written so tightly that they exclude (often unintentionally) the development of assurance colonies that may be needed for some species. It is important to global turtle conservation that these conflicts be minimized.

We can divide the strategies into 3 basic approaches: 1) rare species management; 2) keeping common species common; and 3) crisis management. Furthermore, we have learned much about the threats to turtles and how to combat them. These lessons result in additional key guidelines for both conservation and research directions; the common thread among these guidelines is the need for monitoring both to understand the status of species and to determine if conservation actions are working. The following are 7 conservation action examples from North America, combining these basic approaches and guidelines.

Manage rare species.—Rare species management is the traditional focus of conservation. The primary tool is, of course, native habitat protection and preservation. In the best of circumstances this may be all that is needed. In other cases the habitat may have to be restored and repopulated by animals raised elsewhere, often in captivity. Conservation efforts for the Bog Turtle (*Glyptemys muhlenbergii*) have involved protecting good habitat, restoring degraded habitat, and releasing captive-bred animals that have been raised to a size to offer them a better chance of survival ("headstarting"). Taken together these efforts have resulted in real success in strengthening this species' hold on survival. To aid communication among headstarting efforts, for which trial-and-error management is common, PARC is compiling projects for all herpetofauna (www.parcplace.org). Long-term monitoring of populations is a critical element in the management of both rare and common species.

Manage common species.—More conservationists are focusing efforts on managing common species to keep them common. There are three reasons for this approach. The first is that, as the case of the Passenger Pigeon (*Ectopistes migratorius*) reminds us, being common, even abundant, is no guarantee that a species will never go extinct. Second, we now realize that it is much less expensive to save a species while it is common rather than to wait for it to become rare before acting. The sooner action is taken, the greater the options available are, and when there are more options, one can be more effective. Third, if no one pays attention to a species because it is common, problems and declines may go unnoticed because of a faulty assumption. The Common Box Turtle (*Terrapene carolina*) is generally perceived to live up to its name. But many turtle researchers have emphasized that being complacent about this species is a serious mistake. One of the most important aspects of managing common species is addressing mortality and population fragmentation caused by roads. Fencing roads has proved useful for the Desert Tortoise (*Gopherus agassizii*) and may work for

other species. Road patrols during Diamondback Terrapin (*Malaclemys terrapin*) nesting season are a labor intensive, but mainly successful method for reducing road mortality for that species. The search for creative solutions to this problem continues.

Manage crises.—Environmental crises can affect turtles. The Gulf oil spill of 2010 imperiled sea turtles and those species became icons of the disaster. In fact, the Diamondback Terrapin (*Malaclemys terrapin*) was perhaps even more at risk. There are three subspecies of terrapin living only in the estuaries along the Gulf of Mexico and their narrow ribbon of habitat was affected by oil washing on shore. Although only some populations were affected, terrapin biologists organized and were prepared to move animals out of harm's way if that became necessary. For sea turtles, over 25,000 eggs were moved during the Gulf oil spill, and this proved to be an effective conservation measure (Pittman 2010).

Almost unique to turtles is the crisis management problem presented by large-scale confiscations of illegal animals. Sometimes these confiscations can include thousands of turtles of over a dozen species. Emergency programs by turtle conservationists and veterinarians have been set up to sort, treat and relocate these animals that are often in very poor health.

Regulate commercial turtle harvest.—A recent compilation of herpetofaunal regulations for US states (P. Nanjappa, pers. comm.) shows that little capacity currently exists for coordination or monitoring of harvests of wild or captive herpetofaunal species. There is great variation among state fish and wildlife agencies with some having generally prohibited all commercial exploitation of wild turtles and others offering fewer restrictions. In 2009 and 2010, representatives of many of the US state fish and wildlife agencies met to begin to address regulatory issues and needs. This process will continue in 2011. Sea turtles benefit from federal regulation and funding, due to their rarity and international migratory nature; similar federal protections are afforded to tortoises, and could be considered for freshwater turtles. The US Fish and Wildlife Service is actively engaged in these turtle issues as well, and is a key player, with state fish and wildlife agencies, in the revision of CITES Appendices. Realistically, we may not be able to prevent or ask for bans on all harvest. However, we can encourage and support closely-monitored and well-regulated harvest; with such measures, some commercial turtle harvest could be acceptable.

Turtle farming operations have not been closely monitored or studied. In particular, how much do farms rely on native wild turtles for brood stock? In addition to understanding 'take' in wild populations, a greater understanding of the contribution of US turtle farms to US and world commercial markets is needed. This need is growing as production grows.

Create and institutionalize local interest groups for localized species.—Highly localized species need highly localized support groups; that is, groups of people that champion their local turtle. Such groups, formal and informal, exist for some species. Even in 1952, Archie Carr could write of the Plymouth Red-bellied Turtle population that "If it were not for the interest shown by local inhabitants of Plymouth County in the conservation of this interesting population of turtles it would soon be wiped out." The turtle conservation community needs to facilitate the creation of such groups. For example, this community could help folks living near some of the Gulf South *Graptemys* to develop a sense of pride and appreciation for their neighborhood endemics.

Implement range-wide population, habitat, and risk analyses for widespread species.—GAP Analysis is a conservation evaluation process where the ranges and populations of species are overlaid on protected areas such as National Parks to determine how well protected they are over their entire range. For example, we need a range-wide GAP analysis of the Common Box Turtle (*Terrapene carolina*) to estimate how many populations are currently protected and an assessment of the real risk that this species faces. Data from all states and Canada would be needed for this type of synthesis. The PARC-initiated USA Turtle Mapping Project (www.yearoftheturtle.org) is a necessary preamble for such a large-scale species assessment.

Additionally, a meta-population analysis for widespread species is needed to look for 'tipping points.' Many species of terrestrial turtles and tortoises live in populations that are more or less loosely connected by individuals who move between the local populations. This pattern is called a meta-population, and understanding how meta-populations work, and how they can fail, is an important aspect of the conservation of these species. Connectivity focal areas could be identified in such an analysis. As increasing road traffic prevents any movement from one population to another, isolated populations may have a greater chance of going extinct. We must determine at what point fragmentation of a meta-population causes a species to go extinct, and where the critical connection points exist. Many researchers believe there is a tipping point as meta-populations become increasingly isolated where they can fail and go extinct. We must determine how and when this may be true of turtles, and geographically where the important areas are to maintain connectivity.

Develop methods to assess and ensure high genetic diversity for greater evolutionary potential to respond to global change.—Genetic diversity is the basis of evolutionary adaptation to changing environments. Many turtle environments are predicted to shift under climate change scenarios. The details of these changes as they apply to particular species are generally unknown. With this uncertainty about environmental change, it becomes important to ensure that turtle and tortoise populations are genetically diverse so that they can respond to whatever change does actually occur. This is a strategy of hedging one's bets on the future. Increased efforts are warranted to evaluate turtle genetic diversity and the trade-off between how well-adapted turtles are versus how resilient turtles are to changes based on their genetics (i.e.,

their "adaptedness" versus their "adaptability"). This knowledge is especially important for reintroduction programs where animals may be reared in captivity and then released into the wild.

CONCLUSION

Our turtle heritage is diminishing at a rate outpacing that of other main animal groups. The 2011–Year of the Turtle partnership and campaign is an opportunity to raise awareness for turtles, celebrate our turtle heritage, herald conservation and research successes, and identify gaps in our understanding that can be the focus of future work. We outline seven conservation and research implications of the current turtle crisis, and associated conservation opportunities and actions. If we, the turtle conservation community can accomplish efforts in these selected areas, we can greatly help to sustain species and bolster the recovery of declining turtle species.

Acknowledgments.—We thank Peter Paul van Dijk for help with the IUCN listings, and K. Ronnenberg for editorial assistance. Support was provided by the USDA Forest Service, Pacific Northwest Research Station and the Turtle Conservancy.

Chytrid in a Canopy Amphibian: Picado's Bromeliad Treefrog, *Isthmohyla picadoi* (Hylidae), Persists at a Site Affected by *Batrachochytrium dendrobatidis*

The pathogenic fungus *Batrachochytrium dendrobatidis* (*Bd*) has been implicated as the cause of many global amphibian declines (Berger et al. 1998; Bosch et al. 2001; Briggs et al. 2005; Longcore et al. 1999; Ron and Merino 2000; Skerratt et al. 2007). Central American amphibians have experienced substantial declines (Stuart et al. 2004, 2008) and *Bd* has been identified as the cause in a number of these (Crawford et al. 2010; Lips et al. 2006). A more thorough understanding of the natural history and ecology of *Bd* is still needed, and knowledge of the geographic distribution of this fungal pathogen is important for biological conservation (Adams et al. 2007; Young et al. 2001). Likewise, modes of *Bd* dispersal are poorly understood; amphibians and water sources are implicated as the primary vectors, but birds and soil are potentially important vectors as well (Johnson and Speare 2005). *Bd* has also been implicated in historic die-offs in the highlands of western Panama (Lips 1999; pers. obs) and has been detected in environmental water gathered from both lotic and lentic sources (arboreal phytotelmata) in the region (Cossel and Lindquist 2009).

Picado's Bromeliad Treefrog, *Isthmohyla picadoi* (Dunn 1937), is an arboreal, bromeliad-dwelling species found in primary, secondary, and transitional humid montane forests of Costa Rica and Panama (Duellman 2001; Faivovich et al. 2005; Savage 2002; Solis et al. 2008). Stuckert et al. (2009) found that *I. picadoi* inhabits phytotelmata with source water temperatures that fall within the reproductive thermal range of *Bd* in laboratory settings as found by Piotrowski et al. (2004). The population of *I. picadoi* from the highlands of western Panama studied by Stuckert et al. (2009) persists despite catastrophic declines and extinctions of other amphibian species in the region due to *Bd* (Lips 1999). Although no data on the population exists prior to the arrival of *Bd*, the population currently appears to be stable based on the number of vocalizations heard throughout the study site over multiple years ranging from 2000 to 2008 (pers. obs.). Stuckert et al. (2009) suggested *I. picadoi* may be a potential vector of vertical stream-to-canopy *Bd* zoospore transfer as well as stream-to-terrestrial dispersal. However, their study did not present evidence of *Bd* infection in *I. picadoi*, nor any correlation between infection in *I. picadoi* and presence of *Bd* in phytotelmata. In this study, we set out to determine: 1) whether *Bd* is detectable in the population of *I. picadoi* at the study site described by Stuckert et al. (2009) and Cossel and Lindquist (2009); and if so, 2) the prevalence of infection; and 3) whether any connection exists between *Bd* infections in individual frogs and phytotelmic water sources.

We studied a population of *I. picadoi* immediately north of Guadalupe Arriba, Chiriquí Province, in the Republic of Panama (8.869444°N, 82.566806°W) between 3 and 29 January 2008 [same population as Stuckert et al. (2009)]. Study sites included primary, secondary, and transitional riparian humid forest, ranging in elevation from 1,950 to 2,300 m elevation. Sites were located in a private forest preserve owned by Los Quetzales Lodge and Spa, and in a small forest tract in the Finca Dracula, owned by Andrés Maduro. Both properties border the Parque Internacional La Amistad and Parque Nacional Volcán Barú.

We located *I. picadoi*, via two techniques: 1) randomly searching bromeliads (leaf axils and phytotelmata) at both day and night; and 2) triangulating male nocturnal position immediately after vocalization. Epiphytic bromeliads and mosses were searched at heights ranging from 0 to 33.5 m

above the ground. Trees and epiphytes were searched using three methods: ground searches, ladder searches, and climbs using the Single Rope Technique (SRT) (Maher 2006). Ground searches entailed examining fallen bromeliads or those within standing reach. Ladder climbs employed a 7.3 m extension ladder to access higher bromeliads. Tree climbs using the SRT, which safely reached heights up to 33.5 m, were used to sample bromeliads otherwise inaccessible to ground and ladder searches. For a more detailed discussion of searching methods, data, and three-dimensional forest position in this species, see Stuckert et al. (2009).

Clean nitrile gloves were used when capturing frogs and were changed between handling different individuals. After capture, frogs were kept outside in individual bags to collect any shed skin for 24 h in order to assess individual health. All were kept at ambient temperature, yet protected from rain and potential predation. No frogs exhibited any of the typical symptoms of chytridiomycosis as described in Berger et al. (1999) such as abnormally high epidermal sloughing, reddening of ventral surfaces, lethargy, or loss of righting reflex. Individual frogs were systematically processed as given in Stuckert et al. (2009) and skin swabbing protocols followed Brem et al. (2007). Individual frogs were swabbed dorsally, ventrally, and along limbs and digits with wooden-handled non-adhesive cotton swabs, as suggested by Livo (2004). Although Lee and Cooper (1995) have suggested that the use of wooden medium inhibits PCR amplification, Retallick et al. (2006) did not find this to be the case (both studies used wooden toothpicks to swab their samples). Additionally, *Bd* cultures also were swabbed with wooden-handled non-adhesive cotton swabs and all yielded positive results, indicating that PCR amplification was not inhibited in our study. Therefore we are confident that the swabbing protocol we used did not contribute to false negatives. The cotton tips were removed from the wooden handle of all swabs and placed into a 2 ml screw capped vial with 70% ETOH and labeled. Samples were refrigerated upon return to the United States.

Traditional PCR and qPCR analyses were conducted. DNA from samples containing shed epithelial fragments was prepared from the fragments using genomic extraction protocols outlined by Boyle et al. (2004). Traditional PCR methods, described by Annis et al. (2004), were utilized to detect and amplify *Bd* sequences with the following changes to the PCR reaction: PCR amplifications were performed in 50µl consisting of 0.4 µM of each primer, 1x Roche FastStart *Taq* buffer with 2mM $MgCl_2$, 0.2 mM of each dNTP, and 2.5 U of Roche FastStart *Taq* polymerase enzyme.

Swab samples were prepared for real-time qPCR analysis according to the procedure outlined by Boyle et al. (2004) and Kriger et al. (2006a). However, samples returning positive in singlicate analyses were subsequently analyzed in triplicate to determine relative infection intensity as suggested by Kriger et al. (2006b). Due to the larger-sized swabs used with our collection protocols, nucleic acids were extracted using 75 µl PrepMan Ultra to ensure sufficient supernatant for analysis. We used an Applied Biosystems StepOne™ real-time PCR system to detect and quantify *Bd* sequences. TaqMan Exogenous Internal Positive Control Reagents were used as internal positive controls (VICTM dye, Applied Biosystems No. 4308323, Hyatt et al. 2007) to ensure there was no inhibition of amplification. Positive controls for the amplification of *Bd* DNA were achieved by using standards as described by Boyle et al. (2004) and a negative water control was run on every 48-well PCR plate.

We caught and swabbed 32 individual *I. picadoi*: 15 males, 3 females and 14 juveniles. Preliminary sample analyses using traditional PCR methods indicated the presence of *Bd* in one swab sample which contained visible, but minor shed epithelial fragments. This was similar to other individuals that had similar amounts of epithelial shedding, but not unusually high amounts that would have indicated clinical chytridiomycosis. Independent quantitative PCR analyses confirmed the presence of *Bd* in the same sample (individual), but in none of the other 31 swabs, indicating an infection detection prevalence of 3.125% in our study (7.91×10^{-4}, 1.62×10^{-1}; 95% exact binomial CI). The mean number of zoospore equivalents calculated from triplicate samples drawn from the infected frog was 366.50 ± 150.82 (SE). The sole infected individual was a large adult male (SVL = 34.3 mm/SUL = 32.85) found in a bromeliad 1.5 m off the ground.

Stuart et al. (2008) cite chytridiomycosis as a likely cause of observed declines in *Isthmohyla* and Lips (1998) observed a dying *Isthmohyla calypsa* individual in Costa Rica during the beginning of a local *Bd* epidemic. Although not tested for chytridiomycosis, this individual was likely infected. Further, species distribution modeling by Lötters et al. (2010) has shown that *I. calypsa* and a number of critically endangered congeners (*I. angustilineata, I. debilis, I. graceae, I. rivularis,* and *I. tica*) have geographical ranges that overlap with known localities of *Bd* and their rapid enigmatic decline is associated with chytridiomycosis. Although *Bd* has been implicated in other *Isthmohyla* declines, to our knowledge *Bd* has only been confirmed in *I. pseudopuma* from populations near Monteverde, Costa Rica (Picco and Collins 2007; Puschendorf et al. 2006; JOC, unpubl. data). These findings represent a confirmed second *Isthmohyla* species infected with *Bd* and provide support to the suggestion that amphibians of this genus are susceptible to infection (Lötters et al. 2010). These findings are also significant because they corroborate findings from Cossel and Lindquist (2009) that demonstrated the presence of *Bd* in both lotic and lentic environmental water sources at the same site which has been heavily impacted by *Bd*.

The detection of *Bd* in an extant species in this region has some notable implications. First, the persistence of *I. picadoi* in the Chiriquí highlands of Panama may simply be associated with the species' arboreal life history. The prevalence of infection may be lower in *I. picadoi* than in stream breeding congeners because *I. picadoi* not only lives in bromeliads, but breeds in them as well. Thus, they rarely if ever come into

contact with lotic bodies of water such as streams which are shared by many different amphibian species. This species' life cycle and microhabitat usage might explain why *I. picadoi* persists while formerly sympatric riverine species such as *Rana warszewitschii* and *Atelopus chiriquiensis* were extirpated or may have gone extinct, respectively (Lips 1999). This could also explain why populations of *I. picadoi* seem to remain stable (pers. obs.) despite living in sympatry with *Bd* while congeners that are more closely linked to streams (like *I. calypsa*) are declining or have completely disappeared (Lips 1998). The one frog that tested positive for *Bd* was found in a bromeliad with a significantly elevated zoospore load of 6,780 ± 85 Eq/L (Cossel and Lindquist 2009). The study by Cossel and Lindquist (2009) only found *Bd* in one other bromeliad (4.2% of all bromeliads sampled were *Bd* positive). This bromeliad was near another captured *I. picadoi*; however, *Bd* was not detected on this frog. The low prevalence of *Bd* in bromeliads (Cossel and Lindquist 2009) and the positive *Bd* association between frogs and bromeliads may further support the notion that the canopy presents lower, but not completely eliminated, potential *Bd* exposure risks. The *Bd* positive frog and bromeliad this frog was found in were located roughly 200 m away from the nearest stream (also positive for *Bd*) and raises the possibility that *I. picadoi* may serve as a vector and/or reservoir for *Bd* (although we cannot fully rule out some other vector). Second, an apparently low level of *Bd* prevalence occurs in *I. picadoi*, perhaps suggesting some adaptive and/or innate immune response exists. A discussion of immunity scenarios has been explored in detail by Richmond et al. (2009), and good evidence of antimicrobial peptide and symbiotic cutaneous bacteria in some species exists in the literature (Lam et al. 2010; Rollins-Smith et al. 2002, 2005, 2006). Further evidence is provided by Carver et al. (2010), who have shown that individuals initially infected and showing signs of clinical chytridiomycosis may be able to fully recover, and although aclinical, may still be infected with the pathogen. Finally, some species have been shown to be able to behaviorally thermoregulate, likely to fight *Bd* infections (Richards-Zawacki 2010). Local or regional *Bd* persistence may be explained by reservoir amphibian species that are sublethally infected (Briggs et al. 2005; Daszak et al. 2004; Davidson et al. 2003; Garner et al. 2006; Woodhams et al. 2007) and additionally, not all species that come into contact with the fungus are at risk of clinical chytridiomycosis (Gascon et al. 2007; Stuart et al. 2008). The one frog which tested positive for *Bd* did not show signs of clinical chytridiomycosis and appeared healthy. However, we did not keep frogs long enough to see if they developed clinical chytridiomycosis.

The presence of *Bd* in this canopy-dwelling species provides evidence that some canopy amphibians may serve as vectors for the fungus (Stuckert et al. 2009). Further, it emphasizes the suggestion by Cossel and Lindquist (2009) that arboreal sites may serve as environmental reservoirs, facilitating the persistence of *Bd* in local environments.

Acknowledgments.—We thank C. Alfaro of the Los Quetzales Lodge and Spa, A. Maduro of Finca Dracula, and their staff for their willingness to allow us to conduct research on their properties, as well as providing exceptional hospitality to our research group. We thank the Emerging Scholars Network, the Christian Scholars Foundation, Messiah College, and Northwest Nazarene University for providing funding for this endeavor. We are grateful to the Smithsonian Tropical Research Institute IACUC for reviewing and approving our animal care protocols. We are likewise indebted to La Autoridad Nacional del Ambiente for providing research and collection permits (SE/A-114-07) for this study. Lastly, we thank C. Rutt, M. Rinker, J. Asper, and J. Stone for their assistance in the canopy and specimen/DNA collection, and C. Corbin and K. Luthman for their assistance with the qPCR.

Prevalence and Distribution of *Batrachochytrium dendrobatidis* at Montane Sites in Central Washington State, USA

The fungal pathogen *Batrachochytrium dendrobatidis* (*Bd*) causes mortality in some amphibians (Berger et al. 1998; Nichols et al. 2001) and has been implicated as one cause of amphibian declines (Pounds et al. 2006; Stuart et al. 2004). Recent studies have found *Bd* in Oregon, Alaska, and Idaho, USA, as well as in British Columbia, Canada (Adams et al. 2007; Garner et al. 2006; Pearl et al. 2007; Reeves 2008; http://www.spatialepidemiology.net/Bd-Maps/), but few data are available on its distribution in Washington, USA. *Bd* has been detected in samples collected in western, central and eastern Oregon but was absent from two sites in Washington (Pearl et al. 2007). *Bd* has been detected in the Oregon Spotted Frog (*Rana pretiosa*) in two other sites in southwestern Washington (Hayes et al. 2009; Pearl et al. 2009). In addition, the fungus has been isolated from amphibians associated with large die-offs in the Cascade Range of Washington (Snoqualmie Pass area; R. S. Wagner and J. E. Johnson, unpubl. data). We investigated the prevalence and distribution of *Bd* on Table Mountain in the Blewett Pass area of central Washington (Fig. 1) to assess the presence of *Bd* in the region and to determine the prevalence for local anurans.

We collected anurans from three sites on Table Mountain, Washington (elevation 1430–1550 m), between June and September 2008. The area is characterized by dry coniferous forest with heavy snowfalls (typically 2–3 m). Species collected were the Columbia Spotted Frog (*Rana luteiventris)*, Cascades Frog (*Rana cascadae)* and Northern Pacific Treefrog (*Pseudacris regilla)*. Animals were hand collected during visual surveys and held individually in clean plastic bags until processing. The sample size at each site was determined by plotting the cumulative number of sampled individuals within a species (x-axis) versus cumulative infection rate (y-axis) for that site. Sampling ended once this plot had stabilized at a plateau, because further sampling would have had little effect on the overall estimate of prevalence.

After capture, skin cells were collected from each frog by swabbing its ventral surface vigorously for fifteen seconds. Swabs were stored in sterile 1.5 ml mirocentrifuge tubes filled with 70% ethanol, and kept at -20°C until they were processed. We also recorded snout–vent length, sex, presence of secondary sexual characteristics, and the presence of typical signs of *Bd* infection (e.g., redness, skin lesions, lethargy, etc.; as in Pessier et al. 1999) for each individual. In addition, the digit second from the outside on the right hind limb of each frog was removed to prevent resampling. Toes were preserved in 70% ethanol and frozen at -80°C. Field gear was sterilized between sites and a clean pair of powder-free latex gloves was used per frog to prevent the spread of infection.

To identify the presence of *Bd* in the samples, skin cells were dislodged from swabs by vortexing for 15 sec. The swabs were removed and the remaining mixture was centrifuged at 13,400 rpm for 7 min. The supernatant was removed and the pellet was resuspended in 20 mL distilled water. Approximately 10 ml of this mixture was then mounted on a glass slide and examined using differential interference contrast microscopy for *Bd* zoosporangia. A sample was considered

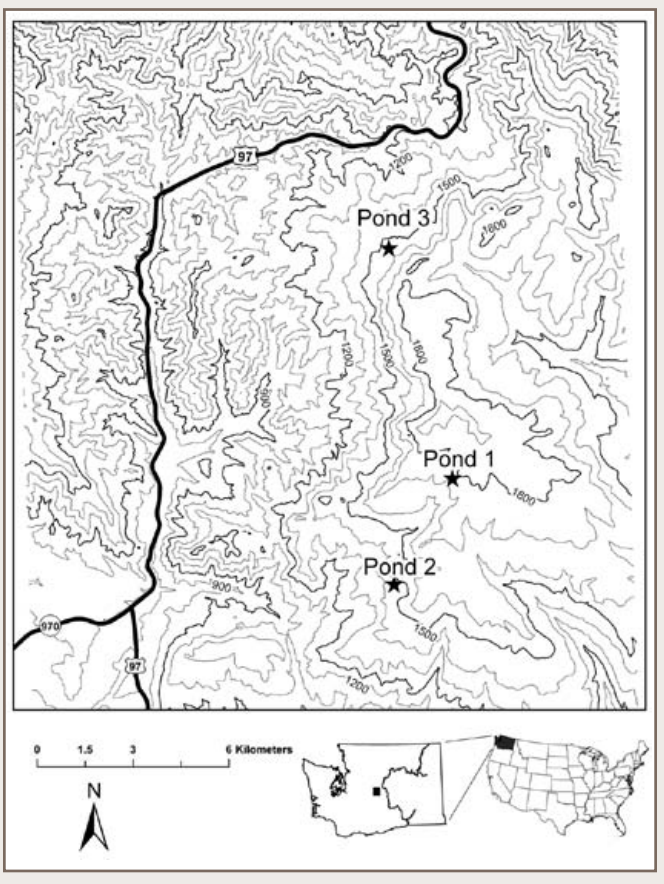

FIG. 1. Sites surveyed for *Batrachochytrium dendrobatidis* on Table Mountain in central Washington, USA, west of the Columbia River (see inset) and east of Highway 97.

TABLE 1. Adult and juvenile amphibians that tested positive (+) or negative (–) for *Batrachochytrium dendrobatidis* in central Washington, USA. Species were *Rana cascadae* (RACA), *Rana luteiventris* (RALU), and *Pseudacris regilla* (PSRE).

Site	Latitude / Longitude	Elevation (m)	Total Sample Size	Species	No. Adults		No. Juveniles	
					+	–	+	–
Pond 1	47.14223°N, 120.34485°W	1760	39	RACA	12	10	2	7
				PSRE	3	5	0	0
Pond 2	47.12467°N, 120.36016°W	1430	22	RACA	0	5	11	4
				PSRE	0	0	1	1
Pond 3	47.18142°N, 120.35890°W	1540	35	RACA	10	8	0	2
				RALU	7	6	1	**1**

negative if no *Bd* structures were found within 10 min. of searching.

We found *Bd* at all sites and in all species sampled. Overall, 49% of the anurans tested positive for *Bd* (Table 1). *Pseudacris regilla* had the lowest infection rate of 40%, whereas *R. cascadae* and *R. luteiventris* had infection rates of 52% and 53%, respectively. Fifty percent of juveniles and 52% of adults tested positive for *Bd*. Across sites, the adult infection rate ranged between 50% and 63%, and the juvenile infection rate ranged between 22% and 50%. None of the differences in infection rate between species, sex, pond site, and life stages were significantly different when compared using contingency tables. No frogs showed the typical signs of infection (i.e., redness, bleeding, lethargy, etc.) and no dead frogs were found during collection.

We report some of the first published accounts of *Bd* in central Washington State, USA and our data are consistent with other studies within the state (Hayes et al. 2009; Pearl et al. 2009), but we observed a higher prevalence than samples from the Northeastern USA (Longcore et al. 2007). Histological methods that sample from clipped toes are known to be less sensitive than PCR methods for detection of *Bd* (Hyatt et al. 2007). We maximized sensitivity by swabbing ventral skin, where zoosporangia are more likely to be found (Berger et al. 2005). Whereas our methods are very unlikely to yield false positives, it is possible that false negatives occurred when infection loads were very light. Considering our conservative methods, our infection rates are very high and consistent with the data of Pearl et al. (2009) for *R. pretiosa*. The high infection rates are very similar between the sites and among the species used in our study. More study is needed to determine if any significant differences exist in *Bd* prevalence at larger spatial and temporal scales (Kriger and Hero 2007). Given that the infected individuals appeared asymptomatic and no dead frogs were found (again similar to the observations of Pearl et al. 2009), the current impact of *Bd* on Washington amphibians is unclear; more study is needed to accurately determine the extent of the threat posed by this pathogen.

Acknowledgments.—This work was financially support by the McNair Scholars program. We thank J. Lamperth for creating the map, Z. Lessig, G. Galindo, J. Galindo, A. Barreca, and B. Hill for help in the field, and J. Johnson for use of his equipment during the study. This work was approved by the CWU Institutional Animal Care and Use Committee (#A09081).

First Detection of Ranavirus in *Lithobates pipiens* in Quebec

Ranaviral disease and chytridiomycosis are emerging infectious diseases implicated in mortality events among wild and captive amphibians (Chinchar 2002; Daszak et al. 1999; Longcore et al. 1999). Ranaviral disease is caused by infection with members of the genus *Ranavirus* and afflicts both larval and adult amphibians (Gray et al. 2009). Chytridiomycosis is a cutaneous disease caused by the fungal pathogen *Batrachochytrium dendrobatidis* (*Bd*) that occurs only in post-metamorphic amphibians, although larvae can be infected (Berger et al. 1998). Both were recently listed as notifiable diseases by the World Organization for Animal Health (Fisher et al. 2009; Gray et al. 2009).

In Canada, amphibian die-offs associated with ranaviruses have occurred in the provinces of Saskatchewan, Manitoba, Ontario, and New Brunswick (Bollinger et al. 1999; Charbonneau 2006; Greer et al. 2005; Forzàn et al. 2009; Jancovich et al. 2005; Schock et al. 2008). *Bd* is present in several Canadian provinces and may have caused population declines in the past (Carey et al. 1999; Deguise and Richardson 2009; Ouellet et al. 2005; Schock et al. 2009). This report describes the incidental detection of ranaviral infection in frogs during their collection for experimental use, the first record of infection of this type in amphibians from Quebec, Canada.

Methods.—In late July 2007, Northern Leopard Frogs (*Lithobates pipiens*) intended for experimental use were caught with nets, in grass and near a pond situated in a privately-owned wildlife preserve in Boucherville, Quebec (45.6477°N, 73.4350°W). Upon capture, small groups were temporarily held in moistened cotton bags and transferred to iceboxes containing pond water. A total of 400 metamorphs and 5 adults were screened for deformities, and except for four unilaterally anophthalmic (missing one eye) and two ectromelic (missing leg below the femur) metamorphs (Table 1), all animals appeared clinically healthy. As only 175 young-of-the-year frogs were required for the planned experiment, these were measured (mean snout–vent length ± SD: 29.95 ± 1.31 mm), transferred to a single icebox holding pond water, and transported to the laboratory. The additional animals were released on site.

In a laboratory held at 22 ± 0.9°C, the froglets were housed in groups of 10 inside tilted 33-L aquariums that contained 2 L of dechlorinated water, to acclimate prior to experimental use. Feces were removed and live crickets were provided daily. Within three days of capture, 7 out of 175 frogs (4%) died; five among them exhibited erythema (i.e., reddening) of the thighs and ventrum. To stabilize the animals, the survivors were individually isolated in 1.84-L plastic shelters containing 50 ml of dechlorinated water, along with platforms to allow them to exit the water. They were also fed crickets injected with tetracycline (50 mg/kg frog weight dissolved in double distilled water) to eliminate potential pathogenic bacterial infections. However, frogs only received half of the recommended dose (i.e. once rather than twice daily) due to time constraints. Mortality reached 40% (70 out of 175 frogs) within eight days of capture, then slowed and was not recorded.

In early August 2007, 100 more juvenile Northern Leopard Frogs were collected from the same site, and they all

TABLE 1. Prevalence (%) of infection by two pathogens and of two types of deformities in juvenile Northern Leopard Frogs (*Lithobates pipiens*) collected in the Parc de la Frayère located in Boucherville, Quebec, Canada, in 2007.

Occurrence	N	Prevalence (%)
Ranavirus	20	85
Batrachochytrium dendrobatidis	20	0
Unilateral anophthalmia	500	0.8*
Ectromelia	500	0.4*

* Five adult frogs that were captured did not exhibit deformities.

appeared healthy. The first 20 were captured by hand, immediately isolated for transport in individual Ziploc® containers holding dechlorinated water, and used only for disease testing; separate gloves were always worn to handle each individual. The other 80 were captured and transported together in an icebox as before, and used to replace dead frogs for the planned experiment.

In the laboratory, the 20 isolated test frogs were swabbed three times over the abdomen, back, thighs, vent, and plantar surfaces of all feet with two sterile cotton swabs. They were immediately killed by immersion in 0.8% tricaine-methanosulfonate (MS-222) and frozen for later necropsy. The swabs were inserted into autoclaved Eppendorf tubes for PCR analysis, to test for ranaviral and *Bd* infections. The other 80 frogs were immediately housed in separate containers, prophylactically administered tetracycline using the same methods and dosage frequency (i.e., once daily) as before, and monitored for signs of disease.

Frog swabs were rehydrated in nuclease-free water for 2 h, vortexed at high speed for one minute and centrifuged briefly. Sample homogenates were then extracted using a QIAamp DNA mini kit (Qiagen, Canada) following manufacturer's specifications. To test for *Bd*, a real-time PCR assay designed to target the ITS1 gene of the fungus (Boyle 2004) was run using an Agpath ID PCR kit (Applied Biosystems, Canada). To test for ranavirus, a conventional PCR assay targeting the major capsid protein (MCP) gene of frog ranavirus (GENBANK Accession Number M19872) was performed using illustra puReTaq RTG PCR beads (GE Healthcare, Canada), and primers designed using DNASTAR software (DNASTAR Inc., USA), at the Department of Veterinary Pathology, Western College of Veterinary Medicine, Saskatoon, Saskatchewan (Anita Quon, pers. comm.). Each bead was hydrated in a total volume of 25 µl containing 1 µl each of forward primer MCP-1 (5'-GCA GGC CGC CCC AGT CCA-3') and reverse primer MCP-2 (5'-GGG CGG TGG TGT ACC CAG AGT TGT-3'). The PCR reaction produced a 482 base pair product which was resolved on a 2% agarose gel and visualized using UV light.

Selected samples that tested positive for frog ranavirus DNA were sequenced by first cleaning the PCR products with a microcon column system (Millipore, Canada). Samples were then diluted 1:10 and run using a Big Dye Terminator v.3.1 cycle sequencing reaction followed by a BigDye Xterminator purification reaction. Purified sequencing samples were run on an Applied Biosystems 3130 genetic analyzer.

Results.—Within 9 weeks of capture, 22 of the 80 (27.5%) newly-captured frogs intended for experimental use died (N = 17) or were killed (N = 5) due to severe ulceration. Signs of disease that the 22 frogs exhibited included anorexia (N = 16), erythema of the hind limbs (N = 16), ulceration on the limbs (N = 5) exposing bone tissue in one case, papillary constriction (N = 1), excessive shedding of the skin (N = 1), petechiation (pinpoint intradermal hemorrhaging) on the chest, and loss of the righting reflex (N = 1). Immediate necropsy of 3 of these frogs revealed white hepatic foci in one case.

Necropsy of the 20 test frogs revealed no signs of disease. However, while the results of the PCR analyses indicated that none of the frogs were infected by *Bd*, 17 of 20 (85%) were infected with a ranavirus (Table 1). DNA sequencing determined the three sequenced viruses to be a 100% match to FV3 (accession number DQ897669) over the PCR target segment.

Discussion.—Our results provide the first documentation of ranavirus infections in Quebec, and suggest that ranavirus can reach a high prevalence (85%) in juvenile Norther Leopard Frogs. While our swab-based screening may have underestimated ranavirus infections, which at least initially may be internal, thus producing false negatives (Gray et al. 2009), the chances of false positives due to surface contamination by virions (Gray et al. 2009) are minimal since the metamorphs were captured on land, where virus persistence outside of hosts is limited, and they were immediately isolated. Our results also suggest, although we cannot be definitive, that these ranavirus infections can be quite lethal. In two groups of metamorphs brought into the laboratory, a sizeable fraction (40% and 27.5%, respectively) died, often with signs that are consistent with ranavirus infection. Only in the latter group was ranavirus identified, and even then we cannot be sure that it was the cause of the mortality, but it is known that *L. pipiens* are susceptible to ranavirus infection (Granoff et al. 1965; Schock et al. 2008), so this seems to be a reasonable hypothesis.

While none of the 20 test frogs tested positive for infection by *Bd*, we were not able to establish that the population was *Bd*-free. Assuming a large population of Northern Leopard Frogs in the area (e.g., 10,000), and given the fact that only 20 frogs were tested for *Bd*, a prevalence of infection as high as 13.9% could have gone undetected in this case (Cannon and Roe 1982). In the surrounding regions of Quebec, prevalence of infection by *Bd* may fall below this level in amphibian populations during the summer and winter months (Ouellet et al. 2005). Thus, although our result may reflect an absence of *Bd* infection in this population (Tennessen et al. 2009; Woodhams et al. 2008), it may also reflect insufficient sampling effort (Speare et al. 2005) or seasonal patterns of infection prevalence (Ouellet et al. 2005).

We recorded four incidences of unilateral anophthalmia among 500 (0.8%) examined froglets. This appears to be a

rare condition in Northern Leopard Frogs, and in amphibians generally (Harris et al. 2001; Hoppe 2000; Johnson et al. 1999; Ouellet et al. 1997; Schoff et al. 2003). Although we did not examine the afflicted eyes for a causal mechanism of the malformation, the ranavirus FV3 was recently associated with reduced eye size in a metamorphic Green Frog (*Lithobates clamitans*) (Burton et al. 2008). Hence, an investigation into possible links between ocular malformations and ranaviral infection may be worthwhile.

In conclusion, juvenile Northern Leopard Frogs from a population in Quebec, Canada tested positive for ranaviral infection without manifesting signs of disease. Untested frogs from the same population developed signs of ranaviral disease (Gray et al. 2009), and some among them died. We cannot affirm ranaviral infection as the cause of death, as a full veterinary diagnostic analysis was not conducted on the dead frogs. It is also not known whether the stress of transport and the captive conditions exacerbated the infections, whether the virus is persistent in this population, or what impact it may be having. It is nonetheless important to note this as the first detection of a ranavirus in an amphibian population from Quebec, making this the fifth Canadian province in which a virus of this type has been found.

Acknowledgments.— LJP was supported by an NSERC Postgraduate Scholarship (PGS M); partial funding for this work was provided by the Pesticide Science Fund and STAGE (Environment Canada). We thank John Robinson (Virology and Molecular Diagnostics, Animal Health Centre, Abbotsford, British Columbia) for PCR analyses and DNA sequencing, Anita Quon (Department of Physiology, Medical Sciences, University of Alberta, Edmonton, Alberta) for advice on PCR analysis, and John Lumsden (Department of Pathobiology, Ontario Veterinary College, University of Guelph, Guelph, Ontario) for advice on veterinary treatment. Partial funding was provided by a Natural Sciences and Engineering Research Council of Canada scholarship to LJP, and by Environment Canada's Pesticide Science Fund (PSF). Permission to collect frog specimens was issued by the Quebec provincial government (Ministère des Ressources Naturelles et de la Faune) (permit number 2007-05-17-789-16-SF). Animals were treated according to the guidelines of the Canadian Council on Animal Care.

Occurrence of *Batrachochytrium dendrobatidis* in Amphibians of Wise County, Virginia, USA

Batrachochytrium dendrobatidis (*Bd*) has been implicated as a deadly pathogen at least partially responsible for global amphibian declines (Berger et al. 1998; Daszak et al. 1999; Stuart et al. 2004). Despite this fungal pathogen being considered as an invasive species (Weldon et al. 2004), we lack knowledge regarding its geographic distribution in many regions (e.g., www.Bd-maps.net). In addition, there is a significant knowledge gap concerning which amphibian species are infected by *Bd* (Steiner and Lehtinen 2008). We address these knowledge gaps by assessing the occurrence of *Bd* in amphibians of Wise County, Virginia, USA. Wise County is located in southwest Virginia, in the heart of the Appalachian Mountains. Amphibian biodiversity, particularly caudate species richness, is high in this region (Lannoo 2005). It is of particular importance to assess the occurrence of *Bd* in the areas of high amphibian biodiversity and endemism because these areas could be more vulnerable to cross-contamination and potential losses. One previous study of *Bd* in Virginia, conducted in the Appalachian Mountains in Warren County, detected *Bd* on only one of 211 salamanders sampled (Gratwicke et al. 2011).

We sampled for *Bd* by collecting toe clips from Wise County, Virginia amphibians from April to September 2010. Toe clips, once collected in the field, were immediately preserved and stored in 1.0 ml of 70% ethanol in 2.0 ml screw-cap vial. In order to avoid cross contamination between toe clippings, all equipment and tools used for toe collection were rinsed in a 10% bleach solution. In addition, nitrile gloves were replaced between each amphibian collected and sampled. Once back in the laboratory, DNA extractions were completed using Promega® Wizard Genomic DNA Purification Kits (Promega® Corporation, Madison, Wisconsin, USA), following the manufacturer's instructions. Amplification of extracted DNA samples was completed using Fisher® BioReagents exACTGene PCR Kits (Fisher Scientific®, Fair Lawn, New Jersey, USA), using specific PCR primers for *Bd* (Bd1a and Bd2a) as reported by Annis et al. (2004). PCR was performed under the following conditions: an initial denaturation of 94°C for 5 min; 30 cycles of denaturation (94°C for 45 sec), annealing (50°C for 45 sec), extension (72°C for 1 min); and a final extension of 72°C for 5 min. PCR products, including both a *Bd* positive and *Bd* negative control, were visualized on ethidium bromide stained 1.0% agarose gel dissolved in 1X TAE buffer under ultraviolet light. A positive *Bd* test was confirmed by the presence of an approximately 300 kb band.

We collected 119 samples from 18 amphibian species (Table 1). Overall, 21 of 119 (17.6%) amphibians tested positive for *Bd*. Specifically, 15 of 21 (71.4%) *Bd*-positive samples were caudates and 6 of 21 (28.6%) were anurans.

To our knowledge, this is the first published report of *Bd* in amphibians of Wise County, Virginia. In addition, we are the first to report *Bd* in several caudate species, including *E. longicauda*, *E. lucifuga*, and *P. cinereus* (although, *Bd* has been documented to infect *P. cinereus* under laboratory settings; Becker and Harris, 2010). *Bd* occurrence here, despite being low, is not altogether surprising given that it has been

reported in Virginia (Gratwicke et al. 2011; Rothermel et al. 2008), Pennsylvania and Tennessee (Groner and Relyea 2010; Todd-Thompson et al. 2009; Venesky and Brem 2008). What is interesting is the comparatively high *Bd* occurrence rate between our study and a recent study conducted in Warren County, Virginia. For example, Gratwicke et al. (2011) report an overall occurrence rate of approximately 2.1% in several caudate species, some of which were sampled for in our study, yet we report an overall occurrence rate of 17.6%. One possible explanation for this difference lies within *Bd* sampling methods. Gratwicke et al. (2011) used cotton-tipped swabs for sample collection, while our study collected tissue samples via toe clipping. Future studies could examine whether there is a *Bd* detectability difference between skin surface swabs versus tissue collection via toe clipping. *Bd* surveillance and amphibian population monitoring should continue in this region to determine the extent and polarity (whether increasing or decreasing over time) of infection in amphibians of the Appalachian Mountains, and potential effects of this infection. Amphibian population losses are alarming; but, in an area of high amphibian endemism such as the Appalachian Mountains, the potential loss of biodiversity is potentially further magnified.

Acknowledgments.—Funding for this project was awarded to SRAD by an undergraduate Fellowship in the Natural Sciences, provided by the Department of Natural Sciences (DNS) at the University of Virginia's College at Wise (UVA Wise). We wish to thank the DNS at UVA Wise for the generous use of their facilities and equipment. Thanks are due to Reid Harris for providing our positive *Bd* control. Amphibian collections were done in compliance with approved protocols from the Institutional Animal Care and Use Committee at UVA Wise and with a Virginia Scientific Collection Permit.

Table 1. Prevalence of *Batrachochytrium dendrobatidis* in amphibians of Wise County, Virginia, USA.

Species	No. infected / total sampled	Prevalence of infection
Caudata		
Desmognathus fuscus	2 / 12	0.167
Desmognathus monticola	1 / 12	0.083
Desmognathus ochrophaeus	1 / 1	1
Desmognathus quadramaculatus	1 / 3	0.333

Batrachochytrium dendrobatidis in *Siren intermedia* in Illinois, USA

We report the first case of *Batrachochytrium dendrobatidis* (*Bd*) in a wild-caught *Siren intermedia* from Illinois, USA. We add to the growing list of amphibian species susceptible to *Bd* infection in North America (Adams et al. 2007; Longcore et al. 2007; Ouellet et al. 2005; Pearl et al. 2007). Examples of fully aquatic salamanders with *Bd* originate from wild populations (*Cryptobranchus alleganiensis*, Briggler et al. 2007, 2008; *Andrias japonicus*, Goka et al. 2009), the pet trade (*Necturus maculosus* and *Siren lacertina*, Speare and Berger 2000), and zoos (*C. alleganiensis*, Briggler et al. 2007; *A. japonicus*, Goka et al. 2009). Internal parasitic helminth infections (McAllister et al. 1994) and two external copepod parasites (Frick 1999; Graham and Borda 2010) have been reported for Sirenidae, but our report is the first infectious disease of any kind reported in a wild-caught animal for this family (Hendricks 2005; Leja 2005; Moler 2005a, 2005b).

We sampled in a roadside ditch along Route 3 in Jackson County, Illinois (37.7241°N, 89.4634°W) on 9 March 2009 (1800–1830 h). Emergent vegetation and accumulated sediments were present, typical of *Siren* habitat (Petranka 1998; Wells 2007). Temperatures of the sampling date varied from 0°C (daily low) to 18°C (daily high); water temperature at time of sampling was 17°C. We captured two *S. intermedia* (SVL_1 = 132.1 mm, $Mass_1$ = 18.5 g; SVL_2 = 75.4 mm, $Mass_2$ = 3.9 g).

We handled sirens with latex powder-free gloves, and kept them in clean plastic sandwich bags filled with on-site water until we completed all data collection on site at which point we released all animals. We gently wiped each animal with a standard rayon-bud swab along their body lengths' ventral surfaces, as well as the front limbs (Hyatt et al. 2007). We stored the swab at room temperature in 70% ethanol until we ran real-time quantitative PCR analysis for *Bd*.

We used standard *Bd* DNA extraction and real-time PCR protocols (Hyatt et al. 2007), except we ran single samples instead of in triplicate to reduce costs (Kriger et al. 2006). Running single samples instead of triplicate is currently accepted as a reliable practice for *Bd* assessment (e.g., Vredenburg et al. 2010; Kriger et al. 2006). We used standards (i.e., 100, 10, 1, and 0.1 zoospore equivalents) and negative controls to ensure repeatability and continuity between runs.

The larger of the two *S. intermedia* that we captured tested positive for *Bd* (3.14 zoospore equivalents) while the other had no infection.

Because of their secretive nature (Petranka 1998) and the lack of population information (Leja 2005), the effect of *Bd* on Sirenidae populations is not known. Previous research on populations of fully aquatic salamanders in natural habitats is limited to *A. japonicus* in Japan (Goka et al. 2009) and *C. alleganiensis* in the Ozark Highlands, USA (Briggler et al. 2008). The former represents a commensal relationship that may have co-evolved with *Bd* over a long time period (Goka et al. 2009), while the latter identifies populations that have experienced declines likely resultant from synergistic negative effects of widespread *Bd* and other biotic and abiotic factors (e.g., habitat degradation, chemical contamination, introduced species, and commercial exploitation) (Briggler et al. 2008). We show that an individual *S. intermedia* carries a low-level *Bd* infection in Illinois. Future research should focus on if the fatal effects of chytridiomycosis are realized in Sirenidae.

Acknowledgments.—We thank S. N. Becker and two reviewers for comments on an early draft of this manuscript, and Erin and Edmund Tucker and T. Hill for field data collection. The laboratories of E. Heist (Southern Illinois University–Carbondale) and V. Vredenburg (San Francisco State University) were used during sample processing and qPCR, and J. Shimp (Illinois Department of Natural Resources) provided logistical support for all aspects of research. Funding by the Illinois Department of Natural Resources, through a State Wildlife Grant (#T-56 R-1), is very much appreciated. Authors have complied with all applicable institutional Animal Care guidelines (Institutional Animal Care and Use Committee Protocol #08-014), and all required state and federal permits have been obtained (IDNR Research Permit #SS09-21).

Salamanders are one of the most important features of America's vertebrate fauna and the Appalachian region of the United States is a global salamander biodiversity hotspot (Young et al. 2004). Despite numerous studies of their biology at the species level, we have a poor understanding of overall threats to salamander biodiversity (Gratwicke 2008). We also have a poor understanding of the susceptibility of different salamander species to diseases, such as the fungus *Batrachochytrium dendrobatidis* (*Bd*). To date, there has been no systematic threat assessment of *Bd* on Appalachian salamanders, but several Appalachian salamander species are known to be susceptible to *Bd* in the wild including: *Ambystoma tigrinum* (Davidson et al. 2003); *Cryptobranchus alleganiensis* (Briggler et al. 2008); *Desmognathus conanti* (Timpe et al. 2008); *D. quadramaculatus* (Bartkus 2009); *D. fuscus* and *D. monticola* (Hossack et al. 2010); *Eurycea bislineata* (Grant et al. 2008); *E. cirrigera* (Byrne et al. 2008) and *Notophthalmus viridescens* (Bakkegard and Pessier 2010; Chatfield et al. 2009; Rothermel et al. 2008; Timpe et al. 2008; J. Ware and K. Duncan, unpubl.data; www.Bd-maps.net). *Bd* can also infect *D. monticola* and *Plethodon metcalfi* (Vazquez et al. 2009); *D. orestes* and *P. glutinosus* (Chinnadurai et al. 2009); and *P. cinereus* (Becker and Harris 2010; Becker et al. 2009) in laboratory settings. The effects of *Bd* on salamanders in both wild

TABLE 1. Salamanders encountered and swabbed to test for *Batrachochytrium dendrobatidis* (*Bd*) as part of the 2009 salamander bio-blitz on the Smithsonian Conservation Biology Institute in Warren County, Virginia, USA.

	Total Counted	Total Swabbed	*Bd* Positives	Number of Sites
Eurycea bislineata	13	13	0	4
Desmognathus fuscus	4	4	0	2
Desmognathus monticola	134	25	1	5
Gyrinophilus porphyriticus	3	3	0	1
Plethodon cinereus	225	142	0	25
Plethodon cylindraceus	21	19	0	7
Pseudotriton ruber	4	4	0	4
Total	404	211	0	34

and laboratory settings, however, are extremely variable depending on temperatures, salamander species, and skin flora (Becker and Harris 2010).

There has been no systematic effort to monitor *Bd* throughout Virginia, although the disease has been detected on amphibians in: 1) Virginia at Mountain Lake Biological Research Station and Upham Brook (Rothermel et al. 2008); 2) the Shenandoah National Park (Grant, unpubl. data); and 3) on A*cris crepitans*, *Lithobates catesbeianus*, *L. clamitans*, *L. spenocephalus*, and *N. viridescens* in Richmond and Charles Counties (J. Ware and K. Duncan, unpubl.data; www.Bd-maps.net). In order to investigate the status of *Bd* and its potential impact on wild salamanders, we surveyed the *Bd* status of salamanders on the 3200-acre Smithsonian Conservation Biology Institute, Front Royal site (SCBI-FR) in Warren County, Virginia (38.893279°N, 78.152381°W). SCBI-FR occupies a low point (elevation range ~300–600 m asl) on the western slope of the Blue Ridge Mountains of Virginia, with a topography characterized by a series of rolling hills and small valleys. Wooded areas are mainly covered by mature secondary Eastern mixed deciduous forest, with Tulip Poplar (*Liriodendron tulipifera*), Pignut Hickory (*Carya glabra*), Black Gum (*Nyssa sylvatica*), Mockernut Hickory (*C. alba*), Red Oak (*Quercus rubra*), and White Oak (*Q. alba*) being the major dominant canopy species.

On 9 May 2009, a salamander bio-blitz event was held for 40 volunteer participants recruited from various local natural history and herpetology groups. Teams surveyed a total of seven stream sites that were selected by dividing each stream on the property into 500-m segments and then selecting stream segments for survey using a random number table. At each survey site, two 25-m transects were sequentially established along one stream bank and all cover objects 1 m either side of the transect line were searched. An additional 27 terrestrial transects were established by dividing the wooded portion of the property (excluding animal enclosures) into 1-km^2 blocks and using a random number generator to select 50 blocks; the transect was placed in the center of each block. At each site, two parallel 25-m transects were established 10-m apart from each other, running in a randomly assigned cardinal direction. All cover objects within 1 m of either side of the transect line were searched. Amphibians encountered in either survey were captured and identified to species level, and fresh powder-free nitrile gloves were used for each animal handled. The first 10 individuals of each species at each site were swabbed for *Bd* by rubbing a cotton-tipped swab 15 times in both directions along the salamanders' ventral surfaces and five times on each foot. Exact GPS coordinates for each specimen were recorded.

Swabs were stored dry at room temperature for four weeks before analysis. Anywhere from one to three swabs were incubated together in an oscillating thermal incubator at 56°C and 30 rpm in 400 µl of lysis buffer and 30 µl proteinase K (Qiagen) for 24 h. After incubation, DNA was extracted from the lysate solutions using a Qiagen Biosprint 96 DNA Blood Kit according to the instructions. Testing for the presence of *Bd* was performed using Qiagen's QuantiTect SYBR Green PCR Kit, using the primers ITS1-3Chytr and 5.8sChytr, developed by (Boyle et al. 2004). Positive and negative controls were included in both the extraction and the realtime-PCR reactions. A melt-curve analysis was used to ensure only *Bd* DNA was amplified. No contamination was present in the DNA or subsequent analysis of these swabs.

Seven salamander species (404 individuals) were encountered in the survey transects, and 211of these individuals were swabbed (Table 1). Only a single *D. monticola* swab tested positive for *Bd* (georeference 38.895383°N, 78.151369°W). Other amphibian species encountered on the property that day during unconstrained searches, but were not swabbed include: *Ambystoma maculatum; Anaxyrus americanus; Anaxyrus fowleri*; *Hyla versicolor*; *Lithobates catesbeianu;*, *Lithobates palustri;*, *Lithobates clamitans*; *Lithobates sylvaticus*; and *Pseudacris crucifer.*

We used a binomial distribution calculator (http://faculty.vassar.edu/lowry/binomialX.html) to calculate the maximum prevalence rate using a 95% confidence limit with our sample of 1 infected swab (success) from 211 salamanders (trials). Assuming 100% detectability on all animals swabbed, we estimate that overall prevalence rates in the combined aquatic and terrestrial salamander assemblage are lower than 2.1%. We did not have sufficient sample sizes to conduct species-specific prevalence rates.

Bd is present in salamanders at very low prevalence rates in Warren County, Virginia. Other studies testing for *Bd* on salamanders in the Appalachians found very low occurrences (Bartkus 2009). The actual level of threat that *Bd* poses to wild Appalachian salamander populations remains an unresolved question. *Bd* is very temperature dependent and varies seasonally, therefore, spring was selected as a time of year when temperatures are optimal for *Bd* (Longcore et al. 2007). The observed prevalence levels of less than 2.1% on the 3200-acre SCBI property at a time of year optimal for detecting the pathogen means that it is unlikely that *Bd* is significantly affecting the salamander populations at that site. Furthermore, our observations in Virginia are consistent with observations elsewhere in the Appalachian region, where others have found that although *Bd* appears to be widely distributed, it is found at low prevalence rates in aquatic salamanders (Bartkus 2009; Byrne et al. 2008; Hossack et al. 2010), but is uncommon in terrestrial salamanders (e.g., Chatfield et al 2009).

Acknowledgments.—We thank A. Crawford for guidance on using the binomial distribution to calculate minimum *Bd* prevalence rates, and over 40 volunteers who helped to sample salamanders. The *Bd* analysis was funded by the Amphibian Taxonomic Advisory Group and the Center for Conservation and Evolutionary Genetics. Swabs were provided by the U.S. Geological Survey.

Batrachochytrium dendrobatidis on the Endemic Frog *Litoria raniformis* in South Australia

Since the end of the 1970s, many mass mortalities and population declines of amphibians in Australia have been attributed to the chytrid fungus, *Batrachochytrium dendrobatidis* (*Bd*; Berger et al. 1998, 2004; Longcore et al. 1999). To date, 29% of 223 (62 native and one introduced species from four families) Australian amphibian species have been found to be infected with *Bd* (Murray et al. 2010). The pathogen is considered to be established in Queensland, New South Wales, Australian Capital Territory, Victoria, Tasmania, and Western Australia, however very little is known about its distribution in South Australia (Murray et al. 2010; Simpkins and Hero 2010; Speare and Berger 2005).

The Southern Bell Frog, *Litoria raniformis*, was once a common frog from southeastern South Australia, the Murray Darling Basin, most of Victoria, the Australian Capital Territory, southwestern New South Wales, and eastern and northern Tasmania (Cogger 1975). However, there are reports of serious declines and local extinctions in New South Wales and Tasmania (Obendorf and Dalton 2006; Wassens 2008), likely due to many factors including increased levels of ultra-violet radiation, possible changes in drought incidence and intensity, predation by the introduced mosquito fish, wetland drainage, and *Bd* (Pyke 2002; Wassens 2008). The species is listed as vulnerable both nationally and in South Australia. In South Australia, *Bd* infection of *L. raniformis* was reported from a captive specimen from Adelaide sampled in 1988 (Speare and Berger 2005) and from a wild-caught specimen from Mount Compass in the Mount Lofty Ranges sampled in 1998 (Murray et al. 2010). In Tasmania the presence of *Bd* in wild populations coincided with the locations of population declines of *L. raniformis*, and the species has been considered highly susceptible to chytrid infection (Obendorf and Dalton 2006; Speare and Berger 2005). Hence the existence of *Bd* in *Litoria raniformis* populations in other bioregions is expected. Also, in a preliminary molecular genetic survey of *L. raniformis*, Vörös et al. (2008) found two distinct genetic groups, one with an inland distribution and a second with a coastal distribution including Tasmania. The two groups have differences in their behavior and ecology (S. Wassens, pers. comm.) and hence could show different environmental sensitivity, including susceptibility to pathogens such as *Bd* (Daszak et al. 1999).

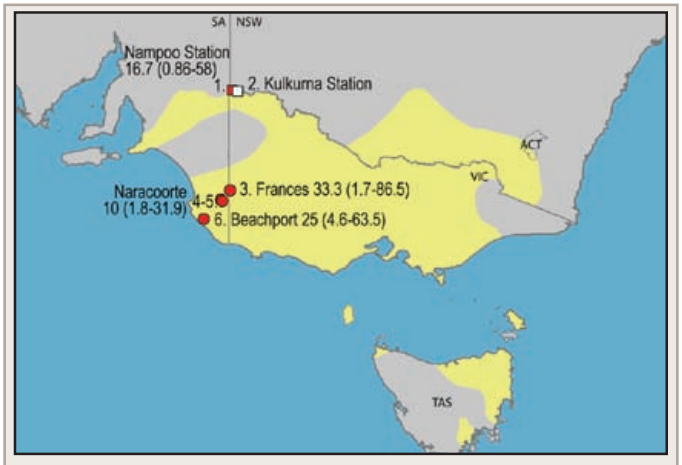

FIG. 1. Historical distribution of *Litoria raniformis* (yellow area) in Australia (after DEWHA 2008 and Thomson et al. 1996), and sampling locations in the Murray Darling Basin (□) and southeastern South Australia (●). Lines represent state borders between South Australia (SA), New South Wales (NSW), Victoria (VIC), Australian Capital Territory (ACT), and Tasmania (TAS). Numbers refer to localities indicated in Table 1. Locations where *Bd* was detected are marked with red and related prevalence and confidence intervals are presented.

Pounds et al. (2006) hypothesized that *Bd* is most prevalent in areas with cool temperature close to the fungus' optimum temperature of 23°C and the constant presence of free water. Hence, within the range of *L. raniformis*, the level of *Bd* infection is expected to be lower in the inland Murray Darling Basin, due to higher maximum temperature and recent extended serious drought conditions, than in coastal populations which have more maritime, cooler and moister, climate conditions (Kriger et al. 2007). The aim of our study was to conduct a pilot survey of the distribution of *Bd* on *Litoria raniformis* in two bioregions in South Australia, the Murray Darling Basin ("Lower Murray") and southeastern (SE) South Australia, representing the two different genetic groups described by Vörös et al. (2008).

We sampled both the Lower Murray and SE South Australia (Fig. 1) regions in early December 2008 and early February 2009. Because *L. raniformis* is active between November and March, our sampling represented the breeding season when frogs gathered in water bodies, which might facilitate the transmission of aquatic chytrid zoospores (Rowley and Alford 2007), and also allowed us to examine metamorphs before they left the water. In the Lower Murray, we sampled

frogs from the Murray River in New South Wales at two sites about 10 km apart at Nampoo Station, in December, and at Kulkurna Station, in February. Unfortunately, low population sizes, especially at Nampoo Station, limited our sampling. In SE South Australia, we sampled frogs from dams or weirs where the number of adult specimens was low. The largest population of *L. raniformis* was found in ponds in a crayfish (*Cherax destructor*) farm on private land in Naracoorte, where we were able to capture 13 adult specimens. Altogether we sampled 8 adults and 70 metamorphs in the Lower Murray (6 adults in December, 2 adults and 70 metamorphs in February), and 35 adults and 64 metamorphs in SE South Australia (28 adults in December, 7 adults and 64 metamorphs in February). We did not find larvae during either sampling period.

We collected samples from adult and juvenile frogs with skin swabs using sterile, single-use 7.5 cm applicators from Defries Industries Pty Ltd (Keysborough, Victoria, Australia). We used new gloves or plastic bags when handling each frog in order to prevent cross-contamination. Each frog was swabbed five times on the back, side, abdomen, groin, and webbing area. The swabs were stored frozen until processing (Van Sluys et al. 2008).

We used real-time PCR (Boyle et al. 2004) to detect *Bd*; this method allowed us to quantify the abundance of zoospores within a sample. We ran every sample in duplicate with a dedicated internal positive control (TaqMan Exogenous Internal Positive Control Reagents) for each sample that helps to identify inhibitors present in the DNA extractions. We considered a sample to contain *Bd* DNA only if both amplifications gave positive results. The templates were run and analyzed on a *Rotor-Gene 6000* real-time rotary analyzer (Corbett Life Science). Genomic equivalents (GE) for all positive samples were estimated from standard curves based on known positive controls, considering 0.1 as the minimum value indicative of infection. We estimated prevalence for each population as the proportion of individuals testing positive with 95% confidence intervals for each prevalence

rate using the software Quantitative Parasitology (Rózsa et al. 2000). The same software was used to conduct a Chi-Square test to compare prevalence between the two regions, and a bootstrap 2-sample t-test (with 2000 bootstrap replications) for comparing mean abundances of zoospores between the two regions, separately for adults and metamorphs.

We detected *Bd* from 1 of 8 adults in the Lower Murray, and from 5 of 35 adults in SE South Australia (Table 1). No metamorphs were *Bd*-positive. We detected inhibition in extracts from three samples. All *Bd*-positive samples were collected in December, and all samples collected in February were *Bd*-negative. *Bd*-prevalence of the adult specimens did not differ between the two regions ($\chi^2 = 0.017$, $P = 0.895$), and the abundances of zoospores between the regions were similar ($P = 0.434$).

Although we detected *Bd* at low levels in natural *L. raniformis* populations in both bioregions of the species distribution in South Australia, the Lower Murray and SE South Australia, our sample sizes were generally low. Skerratt et al. (2008) recommended that sample sizes >59 be used when prevalence is low. Only two of our metamorph samples met this criterion, and *Bd* was not detected on these animals.

Several studies have shown that elevated temperatures and desiccation may limit the spread of the disease (Berger et al. 2004; Laurance et al. 1996). We studied two populations in two sites in the Lower Murray, where habitats are much more exposed to desiccation than in SE South Australia. One site was sampled in December where we detected one *Bd*-positive individual , and one site in February, which seemed to be free from *Bd*. In SE South Australia, which is a coastal bioregion with lower temperature and higher rainfall, a preferred habitat type of *Bd* (Berger et al 2004), we sampled four sites in December. *Bd* was present in 3 of 4 sites. At one site (Naracoorte crayfish farm) we managed to swab both in December (7 adults) and in February (13 adults and 64 metamorphs). Only adult specimens swabbed in December carried *Bd* (2), and no positive samples were found among the adults or metamorphs examined at the end of the summer. This finding is consistent with the hypothesis that summer high temperatures or low rainfall could reduce *Bd* abundance in the environment and on the frogs (Kriger et al. 2007). A more comprehensive assessment of *Bd* on *L. raniformis* is warranted, including a survey across its life cycle incorporating an assessment of seasonal and regional climate influences (Kriger and Hero 2007).

Acknowledgments.—We thank the Field Naturalist Society of South Australia and the South Australian Department for the Environment and Heritage's Wildlife Conservation Fund for their support of our study, and R. Hutchinson for his assistance with Lirabenda Endowment Fund. Significant help in the laboratory or in the field was provided by C. J. Adler, K. Saint, T. Bertozzi, M. Stockwell, M. Schultz, S. Wassens, R. Johnson and B. Crisp. JV was funded by the Hungarian Eötvös State Fellowship.

Ranavirus Outbreaks in Amphibian Populations of Northern Idaho

Ranavirus outbreaks, caused by pathogens in the genus *Ranavirus* (Family Iridoviridae), were the largest single cause of reported amphibian mass mortality events in the United States from 1996–2001 (Green et al. 2002). Mortality events associated with ranaviruses have been documented on five continents and throughout the latitudes and elevations where amphibians occur (Gray et al. 2009). However, the threat of ranaviruses to amphibian and reptile populations in specific regions is still largely unknown (Chinchar 2002; Gray et al. 2009).

In Idaho, ranavirus was first documented as the cause of death for Tiger Salamanders (*Ambystoma tigrinum*) in 2000 near Yellowstone National Park (USGS 2001); however mass mortality events have not been reported since by the USGS National Wildlife Health Center (NWHC) in Idaho or the eastern parts of neighboring Washington and Oregon. In the Palouse region of north Idaho, multiple species of amphibians and aquatic reptiles, including Long-toed Salamanders (*A. macrodactylum*), Tiger Salamanders, Columbia Spotted Frogs (*Rana luteiventris*), Sierran Treefrogs (*Pseudacris sierra*), Western Toads (*Anaxyrus boreas*), Rough-skinned Newts (*Taricha granulosa*), and Painted Turtles (*Chrysemys picta*), co-occur at small man-made ponds where ranavirus could potentially be a threat. Here we report ranavirus outbreaks in two amphibian species (Columbia Spotted Frogs and Sierran Treefrogs) at two ponds in north Idaho during the summer and fall of 2009.

In 2009, we visually-surveyed and trap-surveyed seven ponds in Latah County, Idaho, USA for amphibians during three seasons (spring, summer, and fall). All footwear and field equipment were disinfected using 10% bleach solution between pond visits to inactivate pathogens and prevent transmission of disease between ponds (Bryan et al 2009). During our survey period, we observed mortality events at two of the seven ponds, one documented on 17 July 2009 at Latah Trail Pond (46.4423°N, 116.4818°W) and one documented on 4 October 2009 at Mort Pond (46.4811°N, 116.5838°W).

We collected 14 dead amphibians (Table 1) for disease diagnostics. A new pair of nitrile gloves was used to handle and place each specimen separately in a new container. Specimens were preserved within 1 h of collection; those analyzed using PCR were preserved in 95% ethanol, and those used for histological analysis were preserved in 10% buffered formalin for 25 hours and then transferred into 70% alcohol. Unpreserved samples for inoculating cell lines were processed on the day of collection.

Dead specimens were analyzed by one of three laboratories to employ multiple methods for diagnostics and obtain independent evidence for causes of death. The NWHC

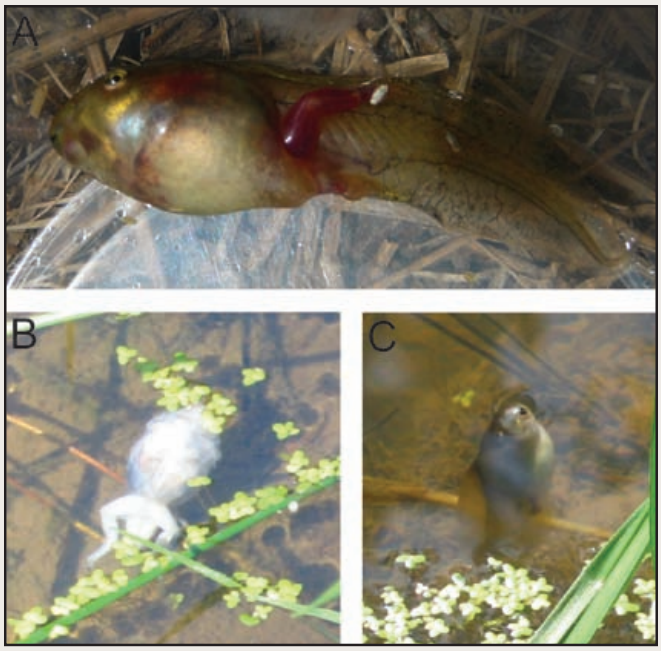

FIG. 1. Tadpoles with ranavirus infection, Latah County, Idaho, USA, 18 July 2009. (A) Columbia Spotted Frog with leg hemorrhage, (B) dead Sierran Treefrog, (C) moribund, bloated Columbia Spotted Frog.

analyzed five specimens using histology. At the NWHC, diagnostics for ranavirus were based on characteristic histological changes in the livers, spleens, mesonephroi, and blood vessels of the frogs. The U.S. Fish and Wildlife Service Idaho Fish Health Center (IFHC) analyzed five specimens using cell culture and PCR. At the IFHC, liver tissue was removed aseptically, ground with a Hank's balanced salt solution (HBSS), spun down, and incubated for 24 hours. Samples were then plated on *Epithelioma papulosum cyprini* (EPC), fathead minnow (FHM), and CHSE-214 (derived from Chinook Salmon) cell lines to culture virus. Ranavirus infection was confirmed using PCR with nested FV3 primers (Bollinger et al 1999; Kattenbelt et al 2000). The Laboratory of Conservation and Ecological Genetics (LCEG) at the University of Idaho analyzed three specimens using PCR and sequencing. To confirm the strain of ranavirus, DNA was extracted from tail-clips of three tadpole samples using a DNeasy Tissue Kit (Qiagen, Inc., Valencia, CA). DNA was amplified using MCP4 and MCP5 primers (Mao et al. 1997), and the resulting 508 base pair PCR product was sequenced with the amplifying primers using a 3130xl Genetic Analyzer (Applied Biosystems, Foster City, CA). Resulting sequences were compared with those in the GenBank database.

On the day before the mortality event was first observed at Latah Trail Pond, we had set 15 minnow traps throughout the pond overnight. We repeated trap sampling on 24 July 2009 at this location to compare amphibian captures seven days after the mortality event was first documented. In addition to trapping, we conducted visual surveys at this pond every other day during the mortality event where one person walked the perimeter of the pond for 5 minutes.

We observed a mass mortality event totaling approximately 200 Columbia Spotted Frog and Sierran Treefrog tadpoles, at least five Long-toed Salamander larvae, and at least seven adult Columbia Spotted Frogs at Latah Trail Pond on 17 July 2009. Another mortality event involving at least 12 adult Columbia Spotted Frogs was observed at Mort Pond on October 4, 2009. Due to the extremely small population sizes of the Columbia Spotted Frog in this system (Davis and Verrell 2005), we also consider the Mort Pond event a mass mortality. The probable cause of death in both cases was infection by ranavirus (Table 1). At Latah Trail Pond, dead and dying amphibians had clinical signs of ranavirus disease, specifically bloated abdomens, leg hemorrhaging, and irregular swimming (Bollinger et al.1999; Docherty et al. 2003; Jancovich et al. 1997; Fig. 1). Histological analyses indicated characteristic changes in livers, spleen, mesonephros, and blood vessels of frogs. DNA sequence for the major capsid protein gene was identical to several frog virus 3 (FV3) sequences (Tan et al 2004), including one from a Northern Leopard Frog (*R. pipiens*; Holopainen et al. 2009) and the *Terrapene carolina* ranavirus (TV3, Mao et al. 1997).

The mass mortality event at Latah Trail Pond lasted at least seven days, with the majority of carcasses found on the first day of observations. By the third day, the majority of amphibian carcasses were gone. Minnow traps at Latah Trail on 17 July captured 63 Long-toed Salamander larvae, 40 Sierran

TABLE 1. Dead amphibians collected from ponds and tested for ranavirus in Latah County, Idaho, following mass mortality events. Species are: Columbia Spotted Frog (CSF) and Sierran Treefrog (ST). Laboratory tests were conducted at the USGS National Wildlife Health Center (NWHC - full necropsy and viral cultures), the Idaho Fish Health Center (IFHC – viral cultures and PCR), and the Laboratory of Conservation and Ecological Genetics (LCEG - PCR and sequencing).

Pond	Date	Species	Age	N	Laboratory	Result
Latah Trail	18-Jul-09	CSF	Tadpole	3	LCEG	Ranavirus
Latah Trail	20-Jul-09	CSF	Metamorph	2	IFHC	Ranavirus
Latah Trail	20-Jul-09	ST	Tadpole	2	IFHC	Ranavirus
Latah Trail	20-Jul-09	CSF	Adult	2	IFHC	Ranavirus
Latah Trail	20-Jul-09	CSF	Adult	2	NWHC	Ranavirus
Mort	4-Oct-09	CSF	Adult	2	NWHC	Ranavirus
Mort	4-Oct-09	CSF	Adult	1	NWHC	Reproductive tract disease

Treefrog tadpoles, and 16 Columbia Spotted Frog tadpoles. Resampling on July 24 yielded only one tadpole and one adult Columbia Spotted Frog. In addition to amphibian mortality, one Painted Turtle at Mort Pond was found alive but lethargic, had difficulty breathing, and was unresponsive to handling, which are consistent with signs of ranaviral disease in turtles with TV3 (De Voe et al. 2004).

This study describes two mass mortality events due to ranavirus in north Idaho. Diagnostic tests indicated that this infectious disease was the cause of mass mortality of Columbia Spotted Frog tadpoles and adults and Sierran Treefrog tadpoles. The presence of sick and dead Long-toed Salamanders and a moribund Painted Turtle during the outbreak suggests that the virus may have affected additional species, however, we did not conduct diagnostic tests on these species. We identified the north Idaho ranavirus as FV3 using sequence from the major capsid protein. Ranaviruses identified as FV3 are multi-host pathogens with a large geographic range in North America (Schock et al. 2008).

Our trapping data indicate that the summer ranavirus outbreak we observed may have removed much of the reproductive output for Latah Trail Pond in 2009. While the drop in trap captures could have been due to metamorphosis during the weeklong mortality event, most tadpoles were several stages from metamorphosis at the beginning of the outbreak (Fig. 1), making this unlikely. As long as ponds in the area do not experience mass mortality events simultaneously or continuously, the high amount of gene flow between sites (Goldberg and Waits 2010) should help maintain population persistence for Columbia Spotted Frogs. Gene flow, however, may also indicate high potential for pathogen transmission. Columbia Spotted Frogs in this region experience a range of stressors and have low numbers of breeding adults (Davis and Verrell 2005). Local populations are subject to aerial spraying of pesticides, disturbance by cattle [which has been shown to increase prevalence of FV3 in Green Frog (*Rana clamitans*) tadpoles (Gray et al. 2007)], and infection by *Bd* (since at least 2004 for Latah Trail and 2005 for Mort; CSG and LPW, unpublished data), among other factors. Additional population monitoring will be required to detect any long-term impacts of the observed mass mortality events on these populations.

Our observations underscore the difficulties of detecting ranavirus outbreaks. Due to variation in timing of metamorphosis and the short time frame in which the visual evidence of mortality was gone (ca. 2 days), it could be difficult to distinguish a mass mortality event from a metamorphosis and dispersal event. Ranavirus outbreaks are therefore likely underreported and may represent a greater threat to native amphibians than currently recognized.

Acknowledgments.—This research was conducted in compliance with an Idaho Department of Fish and Game research collecting permit and a University of Idaho Animal Care and Use Protocol (#2008-55). We thank Erim Gomez for assistance with fieldwork. We thank Hon Ip and Renee Long, USGS National Wildlife Health Center, Madison, Wisconsin, for confirmation of ranaviral infections by culture isolations. HERPETOCULTURE

This section offers a publication outlet for manuscripts involving amphibians and reptiles in a captive environment—public or private. Subjects appropriate for this section include, but are not restricted to, the following:

- Novel techniques for maintenance and reproduction of live herpetofauna
- Genetic management of captive populations
- Legal issues in herpetoculture and animal trade: laws, regulations, permits
- Reviews of tools, equipment, technology, enclosures, etc.
- Safety protocols for working with dangerous species
- Policies and procedures related to preventing transmission of pathogens

Manuscripts that deal exclusively with veterinary medical subjects generally are not appropriate for this section, but consult Section Editor if in doubt.

Manuscripts, ideas, or questions should be directed to the Herpetological Husbandry Section Editors, Brad Lock (block@zooatlanta.org) or Wulf Schleip (wschleip@leiopython.de). All manuscripts will undergo external peer review. For detailed instructions on manuscript preparation, please consult the SSAR web page at: http://www.ssarherps.org/pages/HRinfo.php. When reporting on captive held animals, please also consider the *Guidelines for Use of Live Amphibians and Reptiles in Field Research*, accessible at: http://www.ssarherps.org/pages/HRinfo.php

For authors whose native language is not English and who might require assistance with manuscript preparation, we invite you to consult SSAR's Presubmission Manuscript Review service: http://www.ssarherps.org/page/presub.php.

In addition to conventional manuscripts, we will also publish brief notes based on limited observations of captive animals. These can be considered analogous to Natural History Notes and should be formatted the same way. Please consult that section for formatting guidelines. Subject matter examples include: breeding, courtship, clutch/litter size, gestation, growth, age at first reproduction, longevity, feeding preferences/techniques, thermal biology, unusual behaviors, and so forth. Contributions are welcome from all persons who work with captive amphibians and reptiles, including zoo biologists, private herpetoculturists, and institutional professionals.

Herpetological Review, 2011, 42(2), 226–231.

Although published studies on reproductive data from wild populations of snake species are widely available (Brown and Shine 2007b; Farrell et al. 2009; Luiselli et al. 1996; Madsen and Shine 1996; Slip and Shine 1988), comparatively few publications have presented reproductive data from large populations of captive snakes over multiple years. Specifically in pythons, the studies that have been published on captive populations have generally been on small sample sizes (N < 30 clutches), and have been limited to reporting averages and ranges for reproductive traits (Barker and Barker 2006; de Vosjoli et al. 1994; Ross and Marzec 1990). The larger sample sizes and correlative data generated in studies on wild snake populations have provided researchers with the ability to study various aspects of reproduction such as: optimal clutch

size (Aubret et al. 2003; Brown and Shine 2007b), repeatability of reproductive traits (Brown and Shine 2007b; Farrell et al. 2009; Ford and Seigel 2006), non-linear correlation between female size and snout–vent length (Brown and Shine 2007a; Luiselli et al. 1996; Madsen and Shine 1996), and female reproductive frequency (Farrell et al. 2009; Madsen and Shine 1996; Slip and Shine 1988). Comparable research in captive populations could provide a foundation for the development of captive breeding programs to increase reproductive efficiency. Knowledge such as this has been used to significantly increase breeding efficiencies in livestock animals for decades (reviewed in Hackmann and Spain 2010; Harris 1998). Moreover, an enhanced understanding of python reproductive traits and the correlations between them could increase success in reproducing endangered species, and other species that have been problematic to breed in captivity; such as the Black Python (*Morelia boeleni*) (Austin et al. 2010).

A commercial reptile breeding company, The Snake Keeper, Inc. (Spanish Fork, Utah) has been breeding Ball Pythons (*Python regius*) in captivity for over 20 years. Since 2002 they have been collecting reproductive data on their Ball Python breeding colony. During this time they have collected data on 5344 eggs from 783 clutches. A review of these extensive data provides novel information about Ball Python reproduction and how various reproductive traits are associated with each other. Data presented in the present study on the duration of reproductive events in Ball Pythons are similar to data that have been published previously (Barker and Barker 2006; de Vosjoli et al. 1994; Ross and Marzec 1990). Novel data presented in this study supply information about age at first reproduction, frequency of female reproduction, effects of desiccation on hatch rate, and optimal clutch size. A correlation matrix for reproductive traits is also provided. These data provide a foundation for the design of future experiments, and for enhancing efficiencies of current and future breeding programs.

Materials and Methods.—Adult Ball Pythons were housed in individual cages measuring 81 cm L x 43 cm W x 18 cm H with mesh tops within rack systems (Fig. 1). The substrate used in the caging was chipped aspen bedding. Water was available *ad libitum* and whole prey was offered each week. During the warm months (March to October), the rodents offered were approximately 95 g, and during the breeding season (November to February) they were approximately 65 g. The ambient temperature was controlled from March to October to prevent it from exceeding 29.5°C, and November to February from dropping below 21°C. Throughout the year, a hot spot was available in each cage that was 32°C during the day and 29.5°C at night. Humidity was maintained in the breeding facility at approximately 60% year round by a Humidifirst MP15 ultrasonic humidifier (Humidifirst, Inc., Boynton Beach, Florida).

From November to June, females >1500 g were placed in the cages of males >500 g for one to two days and any observed breeding activity was recorded. An attempt was made

FIG. 2. Female Ball Python brooding a clutch of eggs in which one egg was excluded from her coils.

to ensure that each female was bred at least once each month during this time. Once females were gravid, they were no longer placed with males. The date was also recorded for the following reproductive events when they were observed: ovulation, post ovulation shed, oviposition, and hatching.

Gravid females were checked daily for eggs once they were 30 days past their post-ovulation shed. Eggs were removed immediately from each female, weighed as a clutch, counted, separated, weighed individually, measured (length and width), and placed into an incubation box that was then placed in the incubation room. Each female was also weighed at this time, and a relative clutch mass (RCM) was calculated by dividing the mass of the clutch by the post oviposition mass of the female. The age of the sire and dam at the time of oviposition, when known, was also recorded. From these data, the age at first reproduction was recorded for all the breeders that first reproduced in 2003 or later. In addition, for each female that laid two or more clutches between 2003 and 2009, the number of years between reproductive events (inter-oviposition interval) was recorded as the female reproductive frequency.

The incubation boxes used were Styrofoam shipping containers that measured 28.5 cm L x 39 cm W x 18 cm H externally and were 2.4 cm thick. The incubation medium used in

these boxes was a mixture of one part perlite and two parts vermiculite. Five parts incubation medium to one part water by volume was then mixed, and the box was placed in the incubation room several days prior to incubating eggs in order to allow the contents of the box to reach incubation temperatures. The top of each incubation box was covered with a 1 cm thick pane of glass. The incubation room was temperature controlled by a Helix DBS 1000 (Helix Control Systems, Inc, Vista, California) to stay between 31.4°C and 31.7°C from 2002–2005, and between 30.9°C and 31.1°C from 2006–2009.

Data were also collected per egg on whether the egg was infertile, died during incubation, contained a fully formed embryo that was dead in the egg, embryo was live but deformed, or contained a healthy hatchling. For the eggs that hatched, the hatch date was recorded for each egg and each hatchling was weighed. After hatching, a hatch rate was calculated for each clutch. For the calculation of average oviposition and hatch dates over the years, both oviposition date and hatch date are reported as number of weeks of the year.

GraphPad Prism 5.0 was used for all statistical analyses performed in this study. All traits were analyzed for normality and homoscedasticity and transformations were made when needed. Female mass and clutch mass were log-transformed prior to use in any statistical analyses.

Results.—Data were collected on 5344 eggs from 783 ball python clutches between 2002–2009. Novel information from these data include sire and dam age at first reproduction, dam reproductive frequency, and duration from last copulation to oviposition. A comprehensive summary of clutch, breeder, reproductive event, and egg data is presented in Table 1.

During this study, 27 clutches (3.4%) were recorded as having been found late (> 24 h post oviposition). The clutch mass, RCM, number of healthy offspring, hatch rate, egg length, egg width, and hatchling mass averages were compared between these 27 clutches and averages from all the clutches from this study (Table 2). Student's *t*-test was used on all data except hatch rate for which Mann Whitney test was used due to extreme non-normality.

Oviposition anomalies, such as exclusion of eggs from the dam's coils or early laying of eggs, occasionally occur during the laying season (Fig. 2). Excluded eggs or early eggs were found in 15 (1.9%) and 7 (0.89%) of the clutches, respectively. The RCM, female mass, and clutch mass averages from clutches with one or more eggs found outside the coils of the female and those laid > 24 h prior to the rest of the clutch were compared to the averages from all the clutches from this study (Student's *t*-test) (Table 3). Figure 3 presents the hatch rates calculated for: eggs that were found outside the female's coils (OE), clutches that had eggs pushed outside the coils (OC), eggs that were inside the coils from outside egg clutches (OC - OE), eggs that were laid early (EE), clutches with eggs that were laid early (EC), the eggs that were laid with the majority of the clutch from laid early clutches (EC - EE), and all clutches in this study (ALL). Statistical differences were calculated using the Mann-Whitney test due to extreme non-normality.

In order to analyze relationships between the reproductive traits measured in this study, a Pearson correlation matrix was generated (Table 4). Strengths of correlations are termed as follows: 0.0 to 0.2, negligible; 0.2 to 0.4, weak; 0.4 to 0.7, moderate; 0.7 to 0.9, strong. Among the

28 correlations, 25 (89%) were significant at the P < 0.05 level, and 16 (57%) were above negligible strength (r > 0.2).

Discussion.—Information regarding reproductive traits of captive snakes is sparse. Published reports on pythons are limited to small sample sizes, and to discussing averages and ranges for reproductive traits. Previous studies specifically on ball pythons have reported average clutch sizes, duration from ovulation to post-ovulation shed, duration from post-ovulation shed to oviposition, RCM, egg length, egg width, egg mass, and duration of incubation (Barker and Barker 2006; de Vosjoli et al. 1994; Ross and Marzec 1990; Van Mierop and Bessette 1981). These data have been widely used by private and professional python breeders in order to increase breeding efficiencies. Similar data presented in this study (Table 1) provide larger sample sizes for these traits, and the results are similar to those published previously (Barker and Barker 2006; de Vosjoli et al. 1994; Ellis and Chappell 1987; Ross and Marzec 1990). In addition, this study provides data on the time duration from last copulation to oviposition.

For the 783 clutches studied from 2002 to 2009, an average of 97.88 clutches were laid per year. Although ball pythons in this study appeared to generally be pulse breeders, clutches were laid during all weeks of the year except the first three

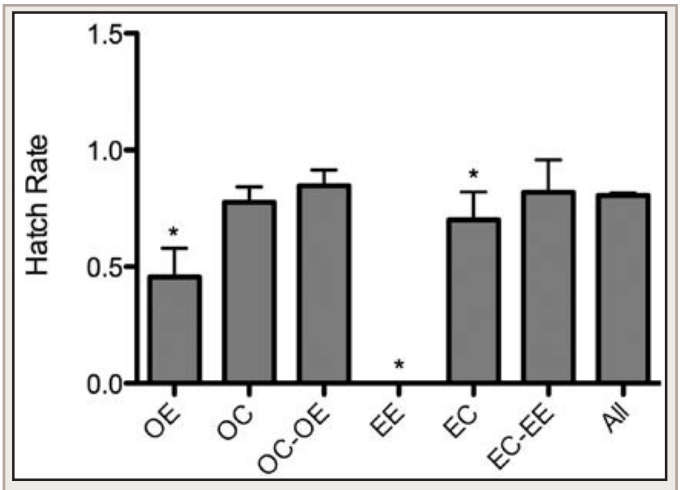

FIG. 3. Hatch rates for eggs that were found outside the female's coils (OE), clutches that had eggs pushed outside the coils (OC), eggs that were inside the coils from clutches with some eggs laid outside the coils (OC - OE), eggs that were laid early (EE), clutches with eggs that were laid early (EC), eggs that were laid with the majority of the clutch from clutches where some eggs were laid early (EC - EE), and all clutches in this study (All). Asterisks denote hatch rates that are significantly different from the overall hatch rate for all clutches from this study (Mann-Whitney test). Bars above columns represent the standard errors of the means.

Correlations in bold were significant at the P < 0.05 level.

weeks in January (Table 1). Further, preliminary data suggest that the week of the year a Ball Python female lays her eggs in captivity is heritable and is significantly affected by both maternal and permanent environmental effects (unpublished data). Reproduction throughout the majority of the year in captive Ball Pythons is in stark contrast to what has been reported to occur in nature. Wild Ball Pythons in southern Togo, Africa generally lay their eggs during one month of the year (Aubret et al. 2003). The fact that female Ball Pythons can proceed through their reproductive cycles at almost any time during the year in captivity could have important implications for those trying to reproduce other python and snake species. Methods such as follicle palpation and ultrasound may significantly enhance success in reproducing these species in captivity by helping to identify times during which males should be introduced to females for copulation. This would be especially important in situations in which keepers are attempting to breed multiple females with single males.

The age at first reproduction (age when oviposition of first clutch occurs) for males in this study varied from 1 to 6 years (average 2.25 years), and for females it varied from 2 to 8 years (average 3.96 years) (Table 1). The average reproductive frequency for females was 1.97 years. Although no data has been published on captive or wild ball pythons for these traits, reproductive frequency has been studied and discussed for other python species. Captive Reticulated Pythons (*Python reticulatus*) and Diamond Pythons (*Morelia spilota spilota*) have been shown to reproduce every other year (Fitch 1970; Harlow and Grigg 1984). Slip and Shine (1988) provided evidence that the reproductive frequency of wild Diamond Pythons was also likely to be every other year, or potentially even longer. In wild Water Pythons (*Liasis fuscus*) reproductive frequency is closer to being yearly (Madsen and Shine 1996). Therefore, a reproductive frequency of every other year in captive Ball Pythons is similar to that found in other python species.

Aubret et al. (2005) incubated Ball Python clutches from wild-bred females by three different methods: maternal brooding until hatching (N = 10), maternal brooding for the first 15 days of incubation followed by artificial incubation (N = 10), and artificial incubation only (N = 10). They observed that the more time clutches were artificially incubated, the more desiccated they became, and hatching success decreased. They concluded that artificial incubation led to desiccation and decreased hatching success. During the current study, 27 clutches were not found until they had been laid for 24 h or more. When the eggs were found, the dam was brooding them. They were then removed from the females and artificially incubated for the remainder of the incubation period. Statistical analysis on averages for clutch mass, RCM, healthy offspring, hatch rate, egg length, egg width, and hatchling mass between these 27 clutches and all the clutches from this study showed evidence for desiccation and decreased hatching success in the clutches that were found late (Table 2). All the traits measured were statistically lower ($P < 0.05$) in the clutches that were found late, except egg length and hatchling mass. Data that suggested desiccation had occurred in clutches that were found late include decreased clutch mass, decreased RCM, and decreased egg width. The decreased hatch rate and number of healthy offspring per clutch suggest lower hatching success in these clutches. In assessment of Aubret et al. (2005), Barker and Barker (2006) suggested that desiccation itself, independent of incubation type, is the cause of decreased hatching success. Because clutches that were found late in this study were desiccated and suffered decreased hatching success even though they were artificially incubated for the majority of the incubation period, these data support the assessment of Barker and Barker (2006).

A previous study by Aubret et al. (2003) assessed optimal clutch size in Ball Pythons. In their study, wild-bred gravid females were caught and brought to a holding facility. Then, ten unmanipulated clutches, nine artificially enlarged clutches (added eggs to increase initial clutch size by 50%), and nine artificially reduced clutches (removed eggs to decrease initial clutch size by 42%) were set up for maternal incubation. Hatching success and hatchling fitness were assessed for the clutches in these three groups. For the clutches that were artificially decreased in size, no benefit to the dam or offspring was detected. However, artificially increasing clutch sizes did significantly decrease hatching success. Therefore, the data from this study suggest that a female's ability to cover her entire clutch is important to hatching success. During the current study, clutch sizes were reduced by the dam when one or more eggs were laid early, or one or more eggs were excluded from the dam's coils during brooding. Although the female mass average from females that produced these reduced clutches was not significantly different from the overall female mass average from all clutches laid in this study, clutch mass was significantly higher in clutches that were laid early, and RCM was significantly higher in both types of reduced clutches (Table 3). Therefore, clutches were reduced in size when they were large in comparison to female mass (higher RCM), which would potentially lead to females experiencing difficulty in covering the proportionately larger clutches. Also, the hatch rate for clutches that had eggs laid early was significantly lower than the hatch rate for all clutches in this study, but the hatch rate for these same clutches once they were reduced (i.e. not including eggs that were laid early) was not significantly different than the overall average (Fig. 3).

Many conclusions can be drawn from the correlations presented in Table 4, but a few we find particularly interesting. Age was correlated at the level of $r > 0.2$ only with female mass, while female mass was also correlated at $r > 0.2$ with clutch size, clutch mass, and EW. This suggests that the mass of the female is more important than age for predicting reproductive output. Further, because female mass was correlated at $r > 0.2$ with clutch size and clutch mass, but not RCM, it seems that the proportion of energy allocated to a clutch is independent of the mass of the female even though both the mass of the clutch and the number of eggs in the clutch

are moderately correlated with the mass of the female (0.50 and 0.56, respectively). Also of interest, EW was correlated at $r > 0.2$ with all traits in the matrix except age. Therefore, EW could be a useful predictor of reproductive output. Lastly, the moderate negative correlation between EL and clutch size, and the weak positive correlation between EW and clutch size support previous research suggesting that as clutch sizes get larger, the eggs get smaller and more round in shape (Brown and Shine 2007b; Ford and Seigel 1989; Madsen and Shine 1996).

The large sample sizes attained in this study have allowed us to study certain aspects of ball python captive reproduction. Novel data presented in this study provide a foundation for the design of future studies, and for the development of more efficient breeding plans for propagating captive pythons. In addition, some specific information presented here can be of immediate use for python propagation. Results from this study suggest that female ball pythons in captivity ovulate in all months of the year. Also, during this study the female reproductive frequency was every other year. Our results also show that desiccation, even for periods of time as short as only a few days, at the beginning of incubation may significantly decrease hatching success. Taking these findings into account, those attempting to propagate pythons in captivity should do the following: 1) Become proficient in techniques such as follicle palpation and ultrasound in order to assess the reproductive stages of females throughout the year; 2) Understand that the reproductive frequency of python females in captivity may be every other year, or even every third year and not push females to reproduce every year; 3) Make provisions in breeding procedures to decrease the risk of subjecting eggs to desiccation at any time during incubation. With further study of some of the correlations presented in this study (e.g. EW correlations), additional information regarding selection parameters to increase breeding efficiencies may be derived as well. Such knowledge will likely lead to increased success in breeding endangered and otherwise rare and difficult to breed python species in captivity.

Acknowledgments.—We are especially thankful to Dan Sutherland for assisting in the gathering and organization of the data collected in this study. We are also very grateful to J. Marcelete Labrum for her help with data entry and suggestions for improving this manuscript. Kimberly A. Elwood and Davin M. Larsen also contributed significantly in improving the quality of this manuscript. Suggestions from Joseph R. Mendelson III, Susannah S. French and two anonymous reviewers were greatly appreciated as well. We would also like to acknowledge the Utah State Agricultural Experiment Station as a source of funding. This publication was approved as UAES publication #8231. All data collection in this study was carried out in accordance with all applicable institutional animal care guidelines. All research for this study adhered to the legal requirements of the United States of America.

HERPETOCULTURE NOTES

CROCODYLIA — CROCODILIANS

***CROCODYLUS RHOMBIFER* (Cuban Crocodile). MATING BEHAVIOR.** Courtship and mating of captive 2.2 m long male and 1.7 m long female *Crocodylus rhombifer* were observed in Zoo Miami (Miami, Florida, USA, 25.60ºN, 80.40ºW) in 2010. The animals were kept in a 20 m^2 concrete pool within a grassy enclosure.

The animals were observed almost daily from 20 March to 15 April, 2010, between 0700–1100 h, from outside the enclosure. All courtship and mating activity was observed between 0830–1000 h from 23–30 March. During seven days of observation with no rain, the male produced six roars (no more than one per day). The roars were produced at the edge of the pool in arched-back posture, and accompanied by body vibrations and "water dance" effect indicative of brief infrasound pulse, as described for Nile (*C. niloticus*) and American (*C. acutus*) Crocodiles (Garrick et al. 1978. Bull. Am. Mus. Nat. Hist. 160:153–192). One of these six roars was followed by a headslap. On one rainy day (when the water temperature was probably lower than usual) the male produced four roars on land. All roars produced in the water were immediately followed by approaches and courtship behavior by the female. In five such cases the male eventually responded with courtship behavior and then mating. The courtship behavior included not only snout- and chin-touching, but also rides around the pool by the female on the back of the male, which were observed on four occasions, and lasted for up to one minute (Fig. 1). Such rides have never been reported for any crocodilian species.

I thank Steven Conners (Zoo Miami) for assistance and the observation permit.

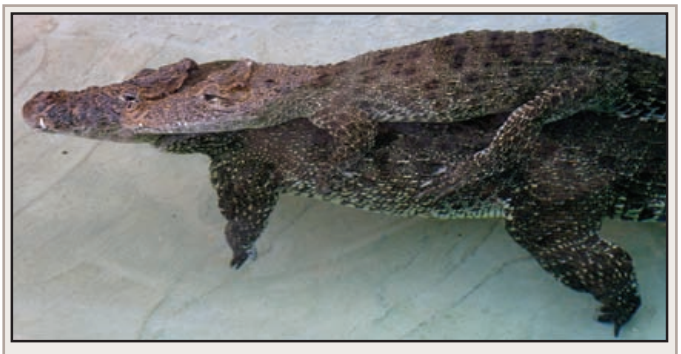

FIG. 1. Female *Crocodylus rhombifer* riding on the male's back during courtship.

TESTUDINES — TURTLES

***INDOTESTUDO FORSTENII* (Forsten's Tortoise). REPRODUCTION.** *Indotestudo forstenii*, a crepuscular tortoise found only on the islands of Sulawesi and Halmahera, is officially listed by the Convention on International Trade of Endangered Species (CITES) Appendix II and by the International Union for Conservation of Nature (IUCN) as an endangered species (Halvorsen 2009. The North American Regional Studbook for the Sulawesi Tortoise, *Indotestudo forstenii*. 2nd ed. West Palm Beach Zoo, West Palm Beach, Florida. 23 pp.). Most of the captive population in zoos consists of wild caught individuals, but a few successful captive breedings have occurred. On 19 March 2010 a wild-caught female housed at the Memphis Zoo with a wild-caught male laid two eggs. Although one of the eggs died, one pipped on 14 August 2010. Six days prior to pipping, a translucent white circle appeared on the egg. Similar translucent patches were observed five, six, and eleven days prior to pipping on three *Gopherus polyphemus* (Gopher Tortoise) eggs that were incubated at the University of Southern Mississippi (pers. obs.). These observations suggest that the appearance of these translucent circles are related to the hatching process and could be used as a way to predict when an egg will hatch. Because zoos attempt to breed tortoise species whose incubation parameters—including incubation duration—are relatively unknown or are widely variable, an indicator of impending pipping would be a useful husbandry tool.

***KINOSTERNIDAE* (Mud and Musk Turtles). GROOMING BEHAVIOR.** Herein, I report multiple instances of self-performed grooming behaviors in captive individuals of at least eight kinosternid taxa in the genera *Sternotherus*, *Kinosternon*, and *Staurotypus*. Behaviors consisted of biting at fore- and hindlimbs, carapacial margins, and areas of reachable skin (all underwater). These taxa have long slender necks with thin loose skin (providing flexibility), and kinetic plastral forelobes that likely facilitate the behaviors described here.

Two adult *Sternotherus minor minor* (1 male, 1 female) were observed on seven occasions (within a month after capture) attempting to remove small turtle leeches (*cf. Placobdella* sp.) from the underside of the nuchal along the ventral scale margin.

FIG. 1. Self-performed grooming session in an adult male *Sternotherus carinatus*. Top) gentle forelimb biting; Center and bottom) biting at skin between the neck and forelimb. This individual has been observed biting at its own nuchal margin and achieving over 180 degrees of head rotation in the process.

FIG. 2. Gentle forelimb biting in an adult male *Kinosternon subrubrum steindachneri*. This individual has been observed removing and eating shedding skin from anterior portions of the body.

Leeches can accumulate in large numbers in this region of the body on *S. m. minor*. Turtles demonstrated the capability of orienting the head 180° laterally through hyperextension and rotation of the neck, so that the nostrils were directed towards the posterior of the body. This enabled the turtles to position their head and jaws under the nuchal margin, and bite, scrape, and even remove leeches from themselves with their jaws. It is unknown if leeches were subsequently consumed, however leeches were observed attached on the inside of the turtles' mouths on the palate and lingual portions of the mandible.

Five adult male *Sternotherus carinatus* were also observed performing similar grooming behaviors, but in the absence of leeches on their bodies. For example, on more than sixteen occasions a large (140 mm CL) individual was observed grooming all reachable portions of its body, including achieving ≥180º head orientation as described above for *S. m. minor*. In such instances, the turtle would repeatedly bite at the anterior margin of its carapace including the outer rim of the nuchal, and gently scrape its lower jaw along the underside of the carapacial rim. During one observation, this turtle began by rotating its head to the left, gently biting at the skin between the neck and forelimb (as seen in Fig. 1), and then biting the margin of the carapace at left marginal scales 1 and 2. It then proceeded to rotate its head even further, biting at the cervical and anterior-most portion of Vertebral Scale 1. This turtle eventually accomplished >180º head orientation, having turned its head to the left side and bitten at right marginal scale 1. Forelimb and hindlimb grooming were most commonly observed in male *S. carinatus*, and pieces of thin sloughing skin were removed and consumed through gentle biting. Hindlimb biting was observed in three individuals and accomplished through hyperextension of the neck either laterally or directly under the body. Standing on the bottom of the enclosure, turtles would straighten out their limbs to position the body off of the substrate. The head and neck were then extended to bite at a hindlimb, often lifting the hindlimb off the substrate in concert to reach the foot. Grooming behaviors lasted between 7–120 seconds.

Six (4 males, 2 females) captive adult *Kinosternon s. steindachneri* were observed briefly self-biting at marginals 1–3 as well as removing shedding skin from forelimbs, the latter being

more commonly observed (Fig. 2). Shedding skin was consumed in forelimb biting. This species frequents xeric wetland habitats that are prone to periods of drought, and it is possible that skin consumption is a resourceful response to this situation. Leeches (cf. *Placobdella* sp.) have also been observed on *K. s. steindachneri* (pers. observ.).

Short bouts of forelimb biting was seen in multiple captive adult individuals of *S. odoratus, Staurotypus salvinii,* and *S. triporcatus*, a male and two female *K. l. leucostomum*, and at least three instances in a young male *K. flavescens*. Grooming intervals for these specimens tended to be relatively short (less than 15 seconds).

Intentional rubbing of the carapace against limestone rocks and cypress wood placed within enclosures was exhibited by four *S. carinatus* on at least six occasions, however these instances lasted for only a few seconds. More passive scraping was also noted when turtles would repeatedly burrow or try to retreat under or adjacent to those objects.

In addition to the taxa reported here, self-performed grooming behavior has been documented for the side-necked turtle *Hydromedusa* (Novelli et al. 2009. Herpetol. Rev. 40:435–436) and it is likely that grooming is (at least in part) a response to heavy ectoparasite loads often borne by many turtle species in the wild. Bottom-dwelling species such as Wood Turtles (*Glyptemys insculpta*), Snapping Turtles (*Chelydra serpentina*), Flattened Musk Turtles (*Sternotherus depressus*), and *S. minor* (Ernst and Lovich 2009. Turtles of the United States and Canada, 2nd ed., Johns Hopkins University Press, Baltimore, Maryland; pers. observ.) often are hosts to dense concentrations of leeches, and *Sternotherus odoratus* has been reported to carry over 20 times the number of leeches as (more commonly) aerial basking species such as the Northern Map Turtle (*Graptemys geographica*) (Ryan and Lambert 2005. J. Herpetol. 39:284–287). The presence of leeches on *Sternotherus* species could be presumed to be energetically costly for such relatively small-sized turtles given that these parasites have been found to consume blood and bone tissues of the host (Siddall and Gaffney 2004. J. Parasitol. 90[5]:1186–1188).

I thank K. Krysko, M. Nickerson, D. Ehret, and A. Hastings (Florida Museum of Natural History) and J. Harding (MSU) for helpful comments on this manuscript. All turtles mentioned here are captive specimens in the private collection of the author and treated under humane conditions.

JASON R. BOURQUE, Florida Museum of Natural History, University of Florida, Gainesville, Florida 32611, USA; e-mail: jbourque@flmnh.ufl.edu.

SQUAMATA — LIZARDS

***SCINCUS SCINCUS* (North African Sand Skink). LONGEVITY.** *Scincus scincus* is a common lizard of Egypt, Libya, and Morocco. The natural life span of this species is currently unknown, but Hughes (1988. J. Herpetol. Assoc. Africa 34:20–24) reported a captive longevity of 5 years, 3 months for this species. Schleich et al. (1996. Amphibians and Reptiles of North Africa. Koeltz Scientific Books, Koenigstein, Germany. 630 pp.) reported a captive life span of 10 years for this species, but gave no specific information to support this.

At the North Carolina Zoological Park, we maintained a female *Scincus scincus* from 27 May 1993 to 5 May 2010. This specimen was obtained from an animal dealer on 27 May 1993 as an adult and was euthanized on 5 May 2010 due to deteriorating health related to old age. At the time of euthanasia the individual had lived at the North Carolina Zoological Park for a period of 16 years, 11 months, and 8 days. This specimen was housed in a 75.6 L. aquarium filled to a depth of 102 mm with loose sand. A heat pad was provided under its off-exhibit enclosure and a 100W incandescent bulb was above the enclosure to provide a basking area. No UV lighting was provided to this animal given its fossorial nature. Water was provided in a shallow dish at all times and the enclosure was misted twice daily to maintain moisture in the sand. Prey items were offered three times/week and consisted of adult crickets, meal worms, and wax worms. All prey items were dusted with several vitamin and mineral supplements (Walkabout Farm's dietary products and Reptivite®) at different times during this period. Because age at time of acquisition was unknown, we cannot estimate age at death although it may have been in the range of 18–20 years.

Three other lizards of the same species that were obtained at the same time from the same source lived for periods of 3 years, 3 months, and 24 days; 5 years, 7 months and 17 days; and 8 years, 8 months, and 9 days. Based on these longevity records, this species may have a natural average life of 10 years as reported by Schleich et al. (1996, *op. cit.*).

We thank Frank Slavens and Roy W. McDiarmid for their help with this note.

EZRA ELLIS (e-mail: ezra.ellis@nczoo.org), JOHN D. GROVES, and MICHAEL OVERLY, North Carolina Zoological Park, 4401 Zoo Parkway, Asheboro, North Carolina 27205, USA.

GEOGRAPHIC DISTRIBUTION

CAUDATA — SALAMANDERS

AMBYSTOMA TIGRINUM (Tiger Salamander). USA: MINNESOTA: Le Sueur Co.: In private pasture 600 m E of 367th Avenue ca. 6.00 km SW of Kasota, MN. (44.24266667°N, 93.99916667°W; WGS 84). 02 July 2010. James Ford Bell Museum (JFBM P379a–b; photographic records). Verified by Kenneth H. Kozak and Christopher E. Smith. Observed by Andrés F Morantes, Otto T Gockman, and Scott A Milburn. First county record updating a pre-1960 voucher from Le Sueur Co. (Oldfield and Moriarty 1994. Amphibians & Reptiles Native to Minnesota. University of Minnesota Press. Minneapolis. 237 pp.). Found under cover board.

ANDRÉS F MORANTES, 4225 Black Oaks Lane N, Plymouth, MN, 55446, USA (e-mail: mora0171@umn.edu); **OTTO T GOCKMAN**, 1280 Raymond Avenue #4, St Paul, Minnesota 55108, USA (e-mail: ogockman@gmail.com).

ECHINOTRITON ANDERSONI (Anderson's Crocodile Newt). JAPAN: RYUKYU ARCHIPELAGO: Amami Island Group: Ukejima Island (28.0333°N, 129.2166°E, ca. 250 m elev.). 5 and 29 March 2010. M. Honda. Graduate School of Human and Environmental Studies, Kyoto University (KUHE) 50691–50693. First island record with voucher. Individuals found inactive underneath pile of withered weeds. Species previously known from Amamioshima and Tokunoshima Islands of the Amami Group, and Okinawajima, Sesokojima and Tokashikijima Islands of the Okinawa Group (Hayashi et al. 1992. Herpetologica 48:178–184), and from Taiwan on the basis of three skeletal specimens deposited in MCZ (Zhao and Adler 1993. Herpetology of China. Contributions to Herpetology [10]. SSAR, Oxford, Ohio. 522 pp. + 48 pl. + 1 folding map). However, this latter record needs verification (Matsui and Ota 1995. Herpetologica 51:234–250). Ukejima Island (13.3 km^2 in area, 398 m elev.) was referred to as another island inhabited by *E. andersoni* but on basis of single photograph, lacking date and locality (Ota and Okada 2003. Reptiles and amphibians. *In* Kagoshima Red Data Book for Animals, pp. 82–116. Kagoshima Environmental Research and Service, Kagoshima, Japan [in Japanese]).

Sampling was conducted under permission from Kagoshima Prefectural Board of Education (reference no. 48 2009; to HO), and supported by grant from Japan Ministry of Education, Science, Sports, Culture and Technology (C-19510238 to MH).

SEEFELT** and **JAMES C. GILLINGHAM**, Department of Biology, Central Michigan University, Mt. Pleasant, Michigan 48858, USA.

NOTOTRITON BRODIEI (NCN). GUATEMALA: IZABAL: Sierra Caral: near Cerro Pozo de Agua (15.39367°N, 88.69183°W; WGS84), 850 m elev. 1 October 2010. Carlos R. Vásquez-Almazán and Jeffrey W. Streicher. Verified by David Wake. Museo de Historia Natural de la Universidad de San Carlos (USAC 2737). This is only the sixth known individual of the species and the locality has the lowest recorded elevation to date; previous low was 1125 m (Campbell and Smith 1998. Sci. Pap. Nat. Hist. Mus., Univ. Kansas 6:1–8). Thus, the elevational distribution of *N. brodiei* is now known to range from 850 m through 1590 m (Kolby et al. 2009. Herpetol. Rev. 40:444), so preserving natural habitats in that range zone is a necessity for its conservation and continued survival. The salamander was caught at ca. 2100 hrs while it was walking across low-lying vegetation in secondary growth forest that was previously covered with tropical deciduous forest.

This report was made possible with funding from Conservation International; collecting permits were issued to C. R. Vásquez-Almazán by Consejo Nacional de Areas Protegidas (CONAP; 001/2010 and 127509).We thank Gustavo Ruano Fajardo, Mónica Barrientos, Obdulio Javier Villagran for field assistance.

CRAUGASTOR CHARADRA (Ranita de Arroyo de la Montaña Noroeste). HONDURAS: SANTA BÁRBARA: tributary of Río Listón (15.533336°N, 88.35014°W; WGS84), 405 m elev. 12 November 2008. James R. McCranie and Leonardo Valdés Orellana. Verified by Steve W. Gotte. USNM 573827–573829. First records for Santa Bárbara (McCranie 2007. Herpetol. Rev. 38:35–39), with the closest known locality being ca. 10 km NE at El Cusuco, Cortés (McCranie 2006. Smithson. Herpetol. Inform. Serv. [137]:ii + 39). The specimens were active at night along a stream surrounded by relatively undisturbed broadleaf forest.

LEONARDO VALDÉS ORELLANA, Gerente General de "Hondufauna," Investigador Privado, Colonia América, Bloque 9, Casa 1806, Comayagüela, MDC, Honduras (e-mail: leovalor@hotmail.com); **JAMES R. McCRANIE**, 10770 SW 164th Street, Miami, Florida 33157–2933, USA (e-mail: jmccranie@bellsouth.net).

CRAUGASTOR RANOIDES (NCN). COSTA RICA: GUANACASTE: Municipality of La Cruz: Península de Santa Elena; Area de Conservación Guanacaste, Quebrada Pedregal 1 (10.9025°N, 85.741667°W; WGS84), 100 m elev. 25 March 2006. H Zumbado-Ulate and F. Soley. UCR 18208. Quebrada Pedregal 2 (10.905278°N, 85.747778°W; WGS84), 80 m. elev. 25 March 2006. H. Zumbado-Ulate and F. Soley. UCR18209. Quebrada Cachimbo (10.908333°N, 85.748333°W; WGS 84), 30 m elev. 19 January 2009. H. Zumbado-Ulate and B. Willink. UCR20555. Quebrada La Amanda (10.532211°N, 85.726111°W; WGS84), 90 m elev. 19 January 2009. H. Zumbado-Ulate and B. Wilink. UCR 20556. Río Canelo (10.912222°N, 85.749167°W; WGS84), 30 m elev. 19 January 2009. H. Zumbado-Ulate and B.Willink. UCR20554. Quebrada Casa de Zinc (10.8375°N, 85.697222°W; WGS84), 150 m elev. 1 May 2009. H. Zumbado-Ulate and B. Willink. UCR20681. All verified by F. Bolaños. First records for the municipality, located ca. 5 km W of the closest known localities in the Municipality of Liberia within the Río Murciélago region (Zumbado-Ulate et al. 2007. Herpetol. Rev. 38:184–185; Zumbado-Ulate et al. 2009. Herpetol. Rev. 40:201). This previously common species throughout Costa Rica has had its populations decimated in recent years due to unknown factors (Puschendorf et al. 2005. Herpetol. Rev. 36:53), so its presence along several rivers and streams within the Península de Santa Elena provides hope that it can be adequately protected; it is considered an endangered species by IUCN. All frogs were found on boulders along slow flowing rocky streams in tropical dry forest.

HÉCTOR ZUMBADO-ULATE (e-mail: hugozu1@yahoo.com) and **BEATRIZ WILLINK** (e-mail: bwillink@gmail.com), Escuela de Biología, Universidad de Costa Rica, Sede Rodrigo Facio, Costa Rica.

HADDADUS BINOTATUS (Clay Robber Frog). BRAZIL: MATO GROSSO DO SUL: Corumbá, Capim Gordura port (18.806871°S, 57.578821°W, datum WGS84), in forested area on the banks of the Paraguay River, about 45 km upstream from the urban area of Corumbá. 27 November 1993. Collected by J. C. Louzan. Coleção Zoológica de Referência da Universidade Federal de Mato Grosso do Sul, Campo Grande, Mato Grosso do Sul, Brazil (ZUFMS AMP0628). Verified by C. F. B. Haddad. *Haddadus binotatus* occurs in eastern and southern Brazil, from southern Bahia state to Rio Grande do Sul state (Brassaloti et al. 2010. Biota Neotrop. 10[1]:275–291; Feio and Caramaschii 2002. Phyllomedusa 1[2]:105–111; Machado and Maltchik 2007. Neotrop. Biol. Cons. 2[2]:101–116; Machado et al. 1999. Rev. Bras. Zool. 16[4]:997–1004; Van Sluys and Rocha 2008. IUCN Red List of Threatened Species, ver. 2010.4. http://iucnredlist.org/). First state record, extends the distribution ca. 840 km W of the Parque Estadual Mata dos Godoy, municipality of Londrina, state of Paraná

(Machado et al. 1999, *op. cit.*) and ca. 920 km W of the Estação Ecológica dos Caetetus, between the municipalities of Gália and Alvilândia, state of São Paulo (Brassaloti et al. 2010, *op. cit.*).

***HYLORINA SYLVATICA* (Emerald Forest Frog)**. CHILE: XI REGION DE AYSÉN: 10 km NE of Villa O'Higgins (48.37153°S, 7249727°W, datum WGS 84; 426 m elev.). Adult male 43.25 mm SVL, collected under logs in Chilean temperate rain forest dominated by *Nothofagus* at the border of Mayer River. 28 January 2010. H. Díaz-Páez. Collection of the Museum of Zoology of the University of Concepción, Concepción, Chile (MZUC-UCCC 36285). Verified by M. Vidal. Species is distributed in Chile from Golfo de Arauco (40.00°S, 72.00°W; Veloso and Navarro 1988. Bull. Mus. Reg. Nat. Torino 6:481–539) to Laguna San Rafael (46.73°S, 73.93°W; Díaz-Páez et al. 2002. Bol. Mus. Nac. Hist. Nat., Chile 51:135–145), and is also reported from the Pacific border of Chiloé Archipielage to Wellington Island (Rabanal and Nuñez 2009. Anfibios de los Bosques Templados de Chile. Universidad Austral de Chile, Valdivia. 206 pp.). This new continental record in the Aysen Region extends the range of the species ca. 220 km SE from Laguna San Rafael and places it on the eastern side of the Patagonian Icefields.

JONATHAN A. **GUZMÁN** (e-mail: jonathanguzman@udec.cl) and **HELEN DÍAZ-PÁEZ**, Departamento de Ciencias Básicas, Campus los Ángeles, Universidad de Concepción, Casilla 341, Los Ángeles, Chile.

***INCILIUS CAMPBELLI* (Sapo del Bosque Noroeste)**. HONDURAS: SANTA BÁRBARA: trubutary of Río Listón (15.51689°N, 88.350086°W; WGS84), 560 m elev. 12 November 2008. James R. McCranie and Leonardo Valdés Orellana. Verified by Steve W. Gotte. USNM 573736. First record for Santa Bárbara (McCranie 2007. Herpetol. Rev. 38:35–39) and helps bridge a distributional gap between localities in the departments of Cortés and Copán (McCranie 2006. Smithson. Herpetol. Inform. Serv. [137]:ii + 39). The specimen was active mid morning on the ground in relatively undisturbed broadleaf forest.

LEONARDO VALDÉS ORELLANA, Gerente General de "Hondufauna," Investigador Privado, Colonia América, Bloque 9, Casa 1806, Comayagüela, MDC, Honduras (e-mail: leovalor@hotmail.com); **JAMES R. McCRANIE**, 10770 SW 164th Street, Miami, Florida 33157–2933, USA (e-mail: jmccranie@bellsouth.net).

***LITHOBATES CLAMITANS* (Green Frog)**. USA: INDIANA: Gibson Co.: Patoka River National Wildlife Refuge and Management Area (38.37256°N, 87.33124°W; NAD 83; Zone 16N). 27 March 2009. Alisha Maves and Randall Haken. Verified by Chris Phillips, Illinois Natural History Survey (INHS 2009ag). New county record (Minton 2001. Amphibians and Reptiles of Indiana. 2nd ed., revised. Indiana Academy of Science. vii + 404 pp.). Single individual caught in a small inundated depression created by a fallen tree.

ALISHA MAVES, **RANDALL HAKEN**, and **LINDSEY LANDOWSKI**, US Fish and Wildlife Service, Patoka River National Wildlife Refuge, 510 1/2 West Morton Street, PO Box 217, Oakland City, Indiana 47660, USA (e-mail: Lindsey_Landowski@fws.gov).

***LITHOBATES CLAMITANS* (Green Frog)**. USA: TENNESSEE: Smith Co.: Hurricane Creek adjacent to Maggarte Road ca. 2.5 km N of Hwy US 70N (36.227797°N, 85.841232°W; WGS 84). 21 March 2011. M. Anderson and A. Carey. Verified by Brian T. Miller. Herpetology Collection at Middle Tennessee State University (MTSU 352A). New county record (Redmond and Scott 1996. Atlas of Amphibians in Tennessee. Misc. Publ. No. 12. The Center for Field Biology, Austin Peay State University, Clarksville, Tennessee. 94 pp. Internet version [http://www.apsu.edu/amatlas] contains links to information regarding Tennessee distribution of amphibians recorded since 1996; accessed 28 March 2010). Adult found in creek.

MICHAEL A. ANDERSON (e-mail: maa3t@mtmail.mtsu.edu) and **ALISON N. CAREY** (e-mail: anc3i@mtmail.mtsu.edu), Department of Biology, Middle Tennessee State University, Murfreesboro, Tennessee 37132, USA.

***LITHOBATES SYLVATICUS* (Wood Frog)**. USA: INDIANA: Pike Co. (38.37114°N, 87.15238°W; NAD83). 22 June 2010. Sarabeth Klueh, Jason Mirtl, Tim Shier, and Lindsey Landowski. Verified by Chris Phillips. Illinois Natural History Survey (INHS 2010o). New county record (Minton 2001. Amphibians and Reptiles of Indiana. 2nd ed., revised. Indiana Academy of Science. vii + 404 pp.). A juvenile was found in a wooded upland area.

TESTUDINES — TURTLES

***APALONE SPINIFERA SPINIFERA* (Eastern Spiny Softshell)**. USA: OHIO: Allen Co.: Amanda Township: Auglaize River 100 m S of State Route 117 (40.707233°N, 84.272914°W; WGS84). 12 September 2010. Cincinnati Museum Center (CMC 12094). Harrison Co.: North Township: Conotton Creek (40.41768°N, 81.14656°W; WGS84). 04 September 2010. CMC 12115. Jefferson Co.: Saline Township: Brush Creek along Pine Grove Road (40.54996°N, 80.71447°W; WGS84). 04 September 2010. CMC 12118. Shelby Co.: Clinton Township: Tawawa Creek 200 m upstream from its confluence with the Great Miami River (40.24918°N, 81.14499°W; WGS84). 12 July 2010. CMC 12095. All specimens were collected by Jeffrey G. Davis and Paul J. Krusling and verified by John W. Ferner. New county records (Wynn and Moody 2006. Ohio Turtle, Lizard and Snake Atlas. Ohio Biol. Surv. Misc. Contr. No. 10. iv + 81 pp.).

JEFFREY G. DAVIS (e-mail: anura@fuse.net) and **PAUL J. KRUSLING** (e-mail:pkrusling@gmail.com) Geier Research and Collections Center, Cincinnati Museum Center, 1301 Western Avenue, Cincinnati, Ohio 45203, USA.

***CHELUS FIMBRIATUS* (Matamata Turtle)**. BRAZIL: MARANHÃO: Tocantins River Basin, Municipality of Estreito (ca. 6.51°S, 47.38°W; datum: SAD 69; 150 m elev.). November 2009. G. Nunan. Museu Nacional, Rio de Janeiro, RJ, Brazil (MNRJ 19411). Verified by U. Caramaschi. This new record is within the Cerrado biome. Species was previously known from the states of Amapá, Amazonas, Pará, Rondônia (on frontier with Bolivia), Mato Grosso, Tocantins e Goiás in Brazil, along the Amazon and north of the Cerrado, and also in Venezuela, Guiana, French Guiana, Colombia, Ecuador, Peru, and Bolivia (Iverson 1992. A Revised Checklist with Distribution Maps of the Turtles of the World. Privately printed, Richmond, Indiana xiii + 363 pp.; Pritchard 2008. *In* Rhodin et al. Chelonian Research Monographs 5:020.1–020.10; Pritchard and Trebbau 1984. The Turtles of Venezuela. SSAR, Oxford, Ohio. vii + 403 pp.). First record for the state of Maranhão in Brazil and the easternmost record, filling a gap along the Tocantins River Basin ca. 570 km S from Belém region (Pará state) and 570 km NE from Luciária / Santa Terezinha region (Mato Grosso state) (Iverson, *op. cit.*; Pritchard, *op. cit.*).

ADRIANO LIMA SILVEIRA, Setor de Herpetologia, Departamento de Vertebrados, Museu Nacional / Universidade Federal do Rio de Janeiro, Quinta da Boa Vista, São Cristóvão, CEP 20940-040, Rio de Janeiro, RJ, Brazil; e-mail: biosilveira@yahoo.com.br.

***CHRYSEMYS PICTA MARGINATA* (Midland Painted Turtle)**. USA: OHIO: Allen Co.: Amanda Township: Auglaize River at Bice Road bridge (40.70035°N, 84.25469°W; WGS84). 13 July 2010. Cincinnati Museum Center Herpetological Photodocumentation Collection (CMC HP 5249). Jefferson Co.: Brush Creek Township: farm pond on State Park Mooretown Rd. (40.59604°N, 80.83760°W; WGS84). 05 September 2010. CMC HP 5247–5248. Both specimens collected by Jeffrey G. Davis and Paul J. Krusling, and verified by John W. Ferner. New county records (Wynn and Moody 2006. Ohio Turtle, Lizard and Snake Atlas. Ohio Biol. Surv. Misc. Contr. No. 10. iv + 81 pp.).

JEFFREY G. DAVIS (e-mail: anura@fuse.net) and **PAUL J. KRUSLING** (e-mail: pkrusling@gmail.com) Geier Research and Collections Center, Cincinnati Museum Center, 1301 Western Avenue, Cincinnati, Ohio 45203, USA.

***DERMATEMYS MAWII* (Central American River Turtle)**. MÉXICO: YUCATÁN: Municipality of Progreso: El Corchito, ca. 31 km N of Mérida (21.281111°N, 89.643056°W; WGS84), ca. sea level. 30 April 2010. Juan Chablé-Santos. Verified by David Lazcano. Photo vouchers, Universidad Autónoma de Yucatán Herpetological Collection (FMVZ-UADY-CH 00001–000028). First record for Yucatán and a 239 km range extension NE of the nearest record at Champotón, Campeche (Lee 1996. The Amphibians and Reptiles of the Yucatán Peninsula. Comstock Publ. Assoc., Cornell University Press. New York. xii + 500 pp.). The turtle was live-captured by hand, photographed, and then released back into a freshwater spring located within a mangrove swamp system.

JUAN B. CHABLÉ-SANTOS (e-mail: jcsantos@uady.mx), **LIZBETH CHUMBA-SEGURA**, and **CELIA SELEM-SALAS**, Universidad Autónoma de Yucatán, Facultad de Medicina Veterinaria y Zootecnia, Campus de Ciencias Biológicas y Agropecuarias, Departamento de Zoología., Km 15.5, Carretera Mérida-Xmatkuil, Yucatán, México.

***GRAPTEMYS GEOGRAPHICA* (Northern Map Turtle)**. USA: OHIO: Van Wert Co.: Washington Township: Little Auglaize River at Township Road 199 bridge (40.858133°N, 84.3975750°W;

WGS84). 13 July 2010. Jeffrey G. Davis and Paul J. Krusling. Verified by John W. Ferner. Cincinnati Museum Center Herpetological Photodocumentation Collection (CMC HP 5259). New county record (Wynn and Moody 2006. Ohio Turtle, Lizard and Snake Atlas. Ohio Biol. Surv. Misc. Contr. No. 10. iv + 81 pp.). Adult and sub-adult basking on emergent log.

JEFFREY G. DAVIS (e-mail: anura@fuse.net) and **PAUL J. KRUSLING** (e-mail: pkrusling@gmail.com), Geier Research and Collections Center, Cincinnati Museum Center, 1301 Western Avenue, Cincinnati, Ohio 45203, USA.

MESOCLEMMYS GIBBA. BRAZIL: PARÁ: Municipality of Parauapebas: Alto dos Carajás (ca. 6.03°S, 50.29°W; datum SAD 69). 16 March 2009. D. F. M. Victor. Museu Nacional / UFRJ, Rio de Janeiro, RJ, Brazil (MNRJ 18105–18108). Verified by U. Caramaschi. This new record is located with the Amazonia biome. The species was previously recorded in Venezuela, Guiana, Suriname, French Guiana, Colombia, Ecuador, and Peru, and in a few localities in the states of Roraima, Amazonas, Acre, and Pará in Brazil (Bour and Pauler 1987. Mesogee 47:3–23; Mittermeier et al. 1978. Herpetologica 34:93–100; Schneider et al. 2009. Herpetol. Rev. 40:236). This new record extends the known geographic distribution of the species about 480 km S of Corcovado, Breves, Pará, the nearest previously reported population (Mittermeier et al., *op. cit.*).

ADRIANO LIMA SILVEIRA, Setor de Herpetologia, Departamento de Vertebrados, Museu Nacional / Universidade Federal do Rio de Janeiro, Quinta da Boa Vista, São Cristóvão, CEP 20940-040, Rio de Janeiro, RJ, Brazil; e-mail: biosilveira@yahoo.com.br.

PSEUDEMYS CONCINNA CONCINNA (Eastern River Cooter). USA: ALABAMA: Crenshaw Co.: Patsaliga Creek at U.S. Hwy 331 N of Luverne (31.72469°N, 86.27813°W). 12 September 2010. Collected by Sean Graham, David W. Hunt, Lindsay V. Adams, and Nicholas C. Craig. Verified by Craig Guyer. AHAP-D 272–273. New county record (Mount 1975. The Reptiles and Amphibians of Alabama. Univ. Alabama Press, Tuscaloosa. 287 pp.). We thank Sean Graham for helping us collect the specimen on our field trip.

DAVID W. HUNT (e-mail: huntmid@auburn.edu), **LINDSAY V. ADAMS**, and **NICHOLAS C. CRAIG**, Department of Biological Sciences, Auburn University, 331 Funchess Hall, Auburn, Alabama 36849, USA.

TERRAPENE CAROLINA (Eastern Box Turtle). USA: GEORGIA: Baldwin Co.: approximately 0.5 km W of Oconee River (33.046236°N, 83.203739°W; WGS84). 01 September 2010. Houston C. Chandler and Dennis Parmley. Florida Museum of Natural History photo voucher (UF 162271). Verified by John B. Jensen. New county record, but within expected range (Jensen et al. 2008. Amphibians and Reptiles of Georgia. University of Georgia Press, Athens. 575 pp.). Single adult male found on forest floor of mixed pine-deciduous forest along Oconee River floodplain.

HOUSTON C. CHANDLER and **DENNIS PARMLEY** (e-mail: dennis.parmley@gcsu.edu), Department of Biological and Environmental Sciences, Georgia College and State University, Milledgeville, Georgia 31061, USA.

TERRAPENE CAROLINA (Eastern Box Turtle). USA: INDIANA: Dearborn Co.: Lubbe Nature Preserve (38.99411°N, 85.11732°W; NAD 83). 12 June 2010. Illinois Natural History Survey (INHS 2010n). Jennings Co.: Calli Nature Preserve (39.00311°N, 85.60933°W; NAD 83). 13 July 2010. (INHS 2010m). Both specimens collected by Sarabeth Klueh, Jason Mirtl, and Tim Shier, and verified by Chris Phillips. New county records (Minton 2001. Amphibians and Reptiles of Indiana. 2nd ed., revised. Indiana Academy of Science. vii + 404 pp.).

SARABETH KLUEH (e-mail: sklueh@dnr.IN.gov), **JASON MIRTL**, and **TIM SHIER**, Wildlife Diversity Section, Indiana Department of Natural Resources Division of Fish and Wildlife, 553 East Miller Drive, Bloomington, Indiana 47401, USA.

TRACHEMYS SCRIPTA ELEGANS (Red-eared Slider). TURKS AND CAICOS ISLANDS: Providenciales: leeward highway near golf course (21.798°N, 72.160°W; WGS84), 10 m elev. 1 October 2009. Brian M. Riggs. Verified by Brian T. Miller. Color photo voucher (APSU 19021). First record from Turks and Caicos Islands (Henderson and Powell. 2009. Natural History of West Indian Reptiles and Amphibians. Univ. Florida Press Florida, Gainesville. xvii + 495 pp.; Schwartz and Henderson 1991. Amphibians and Reptiles of the West Indies: Descriptions, Distributions, and Natural History, Univ. Florida Press, Gainesville. xvi + 720 pp.).

ANOLIS (*NOROPS*) *SAGREI* (Brown Anole). USA: LOUISIANA: St. Tammany Parish: Slidell, Garden Spot Nursery, 770 Robert Boulevard (30.29543°N, 89.76388°W; WGS84). 11 August 2010. C. Thawley. Verified by Kenneth L. Krysko. AUM AHAP-D 297 (digital photograph). New parish record (Dundee and Rossman 1989. The Amphibians and Reptiles of Louisiana. Louisiana State University Press, Baton Rouge. 300 pp.). Adult, captured by hand. Observed in a plant nursery with other adults and juveniles, suggesting presence of breeding population. Corroborates earlier reports that nursery transport is an important vector for invasive *A. sagrei* in Louisiana and elsewhere (Steffen and Birkhead 2007. Herpetol. Rev. 38:353; Williams and Comeaux 2008. Herpetol Rev. 39:366). *Anolis sagrei* has been recorded from six other parishes across southern Louisiana (Meshaka et al. 2009. J. Kansas Herpetol. 32:13–16); the nearest locality is 47 km SW in Orleans Parish (Boundy et al. 2004. Herpetol. Rev. 35:194–196). This new record

is only 11 km W of the Mississippi state line, but 304 km W of the nearest easterly locality in Fort Walton Beach, Florida (Bishop 2005. Herpetol. Rev. 36:336).

CHRISTOPHER J. THAWLEY, Department of Biological Sciences, University of Alabama, Box 870345, Tuscaloosa, Alabama 35487, USA; e-mail: cjthawley@crimson.ua.edu.

CELESTUS BIVITATUS (NCN). HONDURAS: OCOTEPEQUE: El Portillo de Cerro Negro (15.350114°N, 88.633603°W; WGS84), 2100 m elev. 19 August 2008. James R. McCranie and Leonardo Valdés Orellana. Verified by Steve W. Gotte. USNM 573885–86). First records for Ocotepeque. The closest reported locality in Honduras is from ca. 70 km ESE at 18.1 km NW of La Esperanza, Intibucá (see map in McCranie and Wilson 1996. Rev. Biol. Trop. 44:259–264) and ca. 100 km W in Guatemala from near Potrero Carillo, Jalapa (Campbell and Camarillo 1994. Herpetologica 50:193–209). The lizards were active midday in rock crevices on a steep embankment above a trail in cutover broadleaf cloud forest.

JAMES R. McCRANIE, 10770 SW 164th Street, Miami, Florida 33157–2933, USA (e-mail: jmccrani@bellsouth.net); **LEONARDO VALDÉS ORELLANA**, Gerente General de "Hondufauna," Investigador Privado, Colonia América, Bloque 9, Casa 1806, Comayagüela, MDC, Honduras (e-mail: leovalor@hotmail.com).

ENYALIUS BIBRONII (NCN). BRAZIL: MINAS GERAIS: Taiobeiras: 15.867°S, 42.132°W, SAD 69). 6 August 2003. R. N. Feio. Museu de Zoologia João Moojen, Universidade Federal de Viçosa, Viçosa, Minas Gerais, Brazil (MZUFV 409). Joaíma, Fazenda Ramaiana: 16.708°S, 40.816°W. 26 April 2001. R. N. Feio. MZUFV 307. Cristália: 16.749°S, 42.834°W. 1 December 1989. MZUFV 251. Berilo: 16.951°S, 42.463°W. 9 January 1989. MZUFV 249. All verified by M. Trefaut Rodrigues. This species is known to occur in relictual forests of northeastern Brazil, from Ubajara (3.854°S, 40.921°W), state of Ceará to the north, southward to Montezuma, state of Minas Gerais (15.172°S, 42.4973°W) (Jackson 1978. Arq. Zool. 30[1]:1–79; Gogliath et al. 2010. Check List 6[4]:652–654). All new localities are farther south than the previous southernmost records, now updated to Berilo municipality, ca. 195 km straight-line S from Montezuma. Specimens reported here were collected inside forested areas in the Atlantic Forest (MZUFV 307) and ecotonal zones between the Atlantic Forest and the Cerrado morphoclimatic domains (MZUFV 251, 249, and 409).

HENRIQUE CALDEIRA COSTA (e-mail: ccostah@yahoo.com.br) and **RENATO NEVES FEIO** (e-mail: rfeio@ufv.br), Museu de Zoologia João Moojen, Vila Gianetti 32, Universidade Federal de Viçosa, CEP 36570-000, Viçosa, Minas Gerais, Brazil.

HEMIDACTYLUS BROOKII (NCN). HONDURAS: ISLA DEL CISNE: Isla Grande (17.4059°N, 83.9421°W; WGS 84), 12 m elev. 28 April, 5 May 2007, respectively. Jorge A. Ferrari. Verified by Konrad Klemmer. Forschungsinstitut Senckenberg (SMF 90456–57). First records for Isla del Cisne (Powell and Maxey 1990. Cat. Amer. Amphib. Rept. 493.1–493.2). SMF 90456 was caught at night on the walls of a house; SMF 90457 was encountered on a stack of old wood panels.

GUNTHER KÖHLER, Forschungsinstitut und Naturmuseum Senckenberg, Senckenberganlage 25, 60325 Frankfurt a.M., Germany (e-mail: gkoehler@senckenberg.de); **JORGE A. FERRARI**, Organización de Rescate y Protección de Reptiles y Anfibios de Honduras, Tegucigalpa, Honduras (e-mail: herpetoking@yahoo.com).

HEMIDACTYLUS FLAVIVIRIDIS (Yellow-green House Gecko). INDIA: NAGALAND: Kohima (25.6685°N, 94.1056°E, 1432 m elev.). Arya Vidyapeeth Collage Zoological Museum (AVC A1047). 24 September 2010. Verified by S. Sengupta. First record for Nagaland. In India, distributed throughout northern India and westwards but not extending to east of Bengal (Smith 1935. The Fauna of British India, Ceylon and Burma, Including the Whole of the Indo-Chinese Region. Vol. III. Sauria. Taylor & Francis, London. xiii + 440 pp. + 1 pl.). Recent record from Manipur (Harit 2007. Cobra 1[4]:30–32) and Assam (Purkayastha and Das 2009. Herpetol. Rev. 40:451–452), with an assumption of anthropogenic introduction. Observed in a market place, again pointing to a probable human-mediated introduction. Not included in Dasgupta and Raha (2006. Reptilia. *In* J. R. B. Alfred [ed.], Fauna of Nagaland, pp. 433–460. State Fauna Series 12. Zoological Survey of India, Kolkata) indicates a recent introduction. Thanks are due to Kaushik Deuti, ZSI, Kolkata, and Arunabha Bhattacharjee, ZSI, Shillong, for literature support

JAYADITYA PURKAYASTHA, Zoology Department, Arya Vidyapeeth College, Guwahati, Assam, India (e-mail: jaya_ditya@rediffmail.com); **SAPTARSHI MAJUMDER**, Kendriya Vidyalaya, Jagiroad, Assam, India; and **BISWAJIT KUMAR ACHARJEE**, Kendriya Vidyalaya, Dimapur, Nagaland, India (e-mail: biswajitacharjee79@gmail.com).

HEMIDACTYLUS FRENATUS (Common House Gecko). MÉXICO: BAJA CALIFORNIA SUR: Municipality of Mulegé: Santa Rosalía, Hotel El Morro (27.19580°N, 112.14994°W; WGS84), 15 m elev. 25 May 2010. J. B. Granados. Verified by Patricia Galina. Herpetological collection, Centro de Investigaciones Biológicas del Noroeste, La Paz, Baja California Sur, México (CIBNOR 1306–1307). First records for the municipality, extending the known range of this exotic species 197 km N of Loreto (Grismer 2002. Amphibians and Reptiles of Baja California: Including Its Pacific Islands and the Islands in the Sea of Cortez. Univ. of California Press, Berkeley, California. xiv + 399 pp.). Both lizards were collected at night on the hotel wall, along with observing more than 20 other adults, thus indicating a well-established population.

VÍCTOR H. LUJA (e-mail: lujastro@yahoo.com), **JAVIER BRUNO GRANADOS**, and **JOSÉ JUÁN PÉREZ-NAVARRO**, Centro de Investigaciones Biológicas del Noroeste (CIBNOR), Mar Bermejo #195 Colonia Playa Palo de Santa Rita, La Paz, Baja California Sur, 23090, México.

HEMIDACTYLUS FRENATUS (Common House Gecko). HONDURAS: VALLE: Amapala, Isla del Tigre (13.2928°N, 87.6520°W; WGS84), 10 m elev. 14 July 2010. USNM 565827. Isla Exposición (13.3150°N, 87.6741°W; WGS84), 7 m elev. 15 July 2010. USNM 565828–29. Alexander Gutsche, James R. McCranie, and Leonardo Valdés Orellana. All verified by George Zug. First records for Valle. The closest known locality is ca. 50 km E at Choluteca, Choluteca (USNM 570129). USNM 565828–29 were collected midmorning under discarded roof tiles in beach area vegetation, and USNM 565827 was active at night on a hotel wall; many others were observed at both localities. Fieldwork of A. Gutsche was supported by the Adolf and Hildegard Isler Foundation.

LEONARDO VALDÉS ORELLANA, Gerente General de "Hondufauna," Investigador Privado, Colonia América, Bloque 9, Casa 1806, Comayagüela, MDC, Honduras (e-mail: leovalor@hotmail.com); **JAMES R. McCRANIE**, 10770 SW 164th Street, Miami, Florida 33157–2933, USA (e-mail: jmccrani@bellsouth.net); **ALEXANDER GUTSCHE**, Museum für Naturkunde,

HEMIDACTYLUS FRENATUS (Common House Gecko). HONDURAS: ISLA DE LA BAHÍA: Isla de Roatán, Lawson Rock housing development, 6.6 km E of West End (16.33841°N, 86.55511°W; WGS84), 9 m elev. 12 January 2008. Sean M. Rovito. Verified by Theodore Papenfuss. MVZ 263826. First record for Isla de Roatán (McCranie et al. 2005. The Amphibians & Reptiles of the Bay Islands and Cayos Cochinos, Honduras. Bibliomania!, Salt Lake City, Utah. xiii + 210 pp.). The gecko was found at night along with *Phyllodactylus palmeus* and *Sphaerodactylus rosaurae* on a rock wall along the edge of the housing development.

JAMES R. McCRANIE, 10770 SW 164th Street, Miami, Florida 33157–2933, USA (e-mail: jmccrani@bellsouth.net); **SEAN M. ROVITO**, Instituto de Biología, Universidad Nacional Autónoma de México, Tercer Circuito Exterior s/n, AP 70-153, CP04510, México, DF, México (e-mail: smrovito@gmail.com).

HEMIDACTYLUS PARVIMACULATUS (Sri Lankan House Gecko). THAILAND: Bangkok, Suan Luang District (13.711778°N, 100.603986°E, 3 m elev.). Two females (THNHM 17952, 31 January 2011; THNHM 17953, 1 February 2011). Found under cover of a pile of concrete blocks on ground in open lot of urban area. Bangkok, Panthum Wan District, Lumpini Park (13.729047°N, 100.538439°E, 3 m elev.). THNHM 17954, male. 17 February 2010. Under concrete ground cover. Bangkok, Khlong Toei District (13.727208°N, 100.574161°E, 3 m elev.). THNHM 17955, female. 28 February 2011. Found among hedges along walkway of Sukhumwit Road. All specimens collected by Jonathan Hakim. Verified by Tanya Chan-ard. Previously considered a subspecies of *H. brookii,* and separated on basis of molecular (Bauer et al. 2010. Mol. Phylogen. Evol. 57:343–352) and morphological (Rösler and Glaw 2010. Spixiana 33:139–160) evidence. *H. brookii* was recorded from Thailand (Bauer et al. 2002. Herpetol. Rev. 33:322). Separation from *H. brookii* made on basis of number of nasals and of postanal tubercles. THNHM 17953 is gravid, with one developed egg; this along with the number of localities, previous sightings of adults, subadults, and hatchlings, constitute evidence of established population at first location. Other individuals were seen within ca. 150 m radius of first location. Populations in Bangkok likely inadvertently introduced, probably entering via major sea cargo port/sea cargo storage facilities in Khlong Toei District, within 3 km, 4 km, and 2 km of the populations, respectively. First record for Thailand and Southeast Asia. Other recorded localities are in Sri Lanka, southern India (Bauer et al. 2010. Herpetol. J. 20:129:138), and an introduced population in Mascarene Islands, Seychelles (Bauer et al. 2010, *op. cit.*).

MICHAEL COTA, Thailand Natural History Museum, National Science Museum, Technopolis, Khlong 5, Khlong Luang, Pathum Thani 12120 Thailand (e-mail: herpetologe@gmail.com); **JONATHAN HAKIM**, PO Box #2, Kluai Nam Thai PO, Bangkok 10115 Thailand (e-mail: hakim.ndmva@gmail.com).

HEMIDACTYLUS TURCICUS (Mediterranean Gecko). USA: CALIFORNIA: Inyo Co.: Death Valley National Park, Furnace Creek Ranch Hotel, 0.5 km W of Hwy 190 (36.45604°N, 116.87041°W; WGS83; elev. -56 m). 21 April 2007. Ian W. Murray. Verified by Neftali Camacho. Natural History Museum of Los Angeles Co. (LACM PC 1545–1546). New county record (Stebbins 2003. A Field Guide to Western Reptiles and Amphibians. 3rd ed. Houghton Mifflin, Boston, Massachusetts. 533 pp.). Between 2006 and 2008 multiple *H. turcicus* were seen nocturnally active on building walls here. The aforementioned specimen was found while actively foraging on the illuminated wall of a hotel building. In their detailed survey of Death Valley National Park amphibians and reptiles, Persons and Nowak (2006. Inventory of Amphibians and Reptiles at Death Valley National Park. Report to National Park Service. USGS Colorado Plateau Research Station, Flagstaff, Arizona) list *H. turcicus* as being a species of possible occurrence, and discuss a third party sighting of an unidentified gecko climbing a wall at Scotty's Castle, Death Valley as probably being a *Coleonyx variegatus* after repeated searches failed to document *H. turcicus* .

IAN W. MURRAY, MSC03 2020, Department of Biology, 1 University of New Mexico, Albuquerque, New Mexico 87131-0001, USA; e-mail: imurray@unm.edu.

IGUANA IGUANA (Common Green Iguana). TURKS AND CAICOS ISLANDS: Providenciales: east side of island, near Long Bay (21.780°N, 72.166°W; WGS84), 11 m elev. 1 October 2009. Brian M. Riggs. Verified by A. C. Echternacht. Color photo voucher (APSU 19019). First record for Turks and Caicos Islands. The closest reported localities in the West Indies are from the Cayman Islands and Puerto Rico (Schwartz and Henderson 1991. Amphibians and Reptiles of the West Indies: Descriptions, Distributions, and Natural History. University of Florida Press, Gainesville. xvi + 720 pp.)

R. GRAHAM REYNOLDS, Department of Ecology and Evolutionary Biology, University of Tennessee, Knoxville, Tennessee 37996, USA (e-mail: rgraham@utk.edu); **BRIAN M. RIGGS**, Department of Environment and Coastal Resources, Turks and Caicos Islands Government, Lower Bight Road, Providenciales (e-mail: bmr@tciway.tc).

LEPIDOPHYMA MAYAE (Maya Night Lizard). HONDURAS: SANTA BÁRBARA: tributary of Río Listón (15.533336°N, 88.350144°W; WGS84), 405 m elev. 12 November 2008. James R. McCranie and Leonardo Valdés Orellana. Verified by Steve W. Gotte. USNM 573973. First record for Santa Bárbara and only the second record from Honduras; the other locality is from ca. 95 km SSW at San Isidro, Copán (McCranie 2004. Herpetol. Bull. 90:10–21). The lizard was inside a rotten log overhanging a stream surrounded by relatively undisturbed broadleaf forest.

JAMES R. McCRANIE, 10770 SW 164th Street, Miami, Florida 33157–2933, USA (e-mail: jmccrani@bellsouth.net); **LEONARDO VALDÉS ORELLANA**, Gerente General de "Hondufauna," Investigador Privado, Colonia América, Bloque 9, Casa 1806, Comayagüela, MDC, Honduras (e-mail: leovalor@hotmail.com).

LIOLAEMUS XANTHOVIRIDIS (Rawson Lizard). ARGENTINA: CHUBUT: Escalante Department: Provincial Route 27, 33.1 km N junction with Provincial Route 25, 55.1 km N Nollman Bridge over Río Chico (44.93433°S, 68.02661°W; WGS84; elev. 381 m.). 4 November 2008. L. J. Avila and M. Nicola. Herpetological collection of Centro Nacional Patagónico, Puerto Madryn, Chubut, Argentina (LJAMM-CNP 11078–11080). Escalante Department: Provincial Route 27, 60 km N junction with Provincial Route 25 (44.72872°S, 67.90667°W; WGS84; elev. 349 m.). 10 February 2008. L. J. Avila, C. H. F. Pérez, M. F. Breitman, and N. Feltrin. LJAMM-CNP 10296–10303. All verified by C. H. F. Pérez. The type locality is 18 km SW from Dos Pozos (Chubut Province) and the species occurs on the xerophytic coast between northern Río Chubut

and southern Bahía Santa Cruz, extending inland to the Gran Laguna Salada (Mártires Department) basin through the flat embossment of Meseta de Montemayor and extends to about 44°S near Cabo Raso (Florentino Ameghino Department), on the Atlantic shore (Cei and Scolaro 1980. Herpetology 14[1]:37–43). Although the geographic range of this species is poorly known, present confirmed distribution includes Rawson, Gaiman, and Florentino Ameghino departments (Abdala 2007. Zootaxa 1538:1–84). Vouchered specimens from inland localities for this species are scarce. The present records are the first for Escalante Department, extending the known distribution about 235 airline km SW from the nearest vouchered record (FML 17033; Abdala 2007, *op. cit.*), and are the southwestern most localities for Chubut Province and for Argentina.

IGNACIO MINOLI (e-mail: minoli@cenpat.edu.ar), and **LUCIANO JAVIER AVILA** (e-mail: avila@cenpat.edu.ar), Centro Nacional Patagónico, Boulevard Almirante Guillermo Brown 2915, Puerto Madryn, Chubut, Argentina.

MESOSCINCUS MANAGUAE (NCN). HONDURAS: VALLE: Isla Exposición (13.3150°N, 87.6741°W, WGS84), 7 m elev. 15 July 2010. Alexander Gutsche, James R. McCranie, and Leonardo Valdés Orellana. Verified by Steve W. Gotte. USNM 565830–31). First records for Valle. The closest known locality in Honduras is about 19 km E at Punta Ratón, Cortés (Cruz et al. 1979. Herpetol. Rev. 10:26). The lizards were collected midday in heavily disturbed deciduous forest; one was under a log and the other was sunning on a tree stump. Fieldwork of A. Gutsche was supported by the Adolf and Hildegard Isler Foundation.

LEONARDO VALDÉS ORELLANA, Gerente General de "Hondufauna," Investigador Privado, Colonia América, Bloque 9, Casa 1806, Comayagüela, MDC, Honduras (e-mail: leovalor@hotmail.com); **JAMES R. PLESTIODON FASCIATUS (Common Five-lined Skink). USA: ILLINOIS: Calhoun Co.: McCully Heritage Project, 70 m N of Crawford Creek Hollow Rd., 1.15 km W of Hwy 100 (39.282653°N; 90.622480°W; WGS84 datum). 11 April 2009. C. E. Montgomery and P. J. Muelleman. Verified by Chris Phillips. Illinois Natural History Survey collection (INHS 2009.08 photo voucher). First county record since 1954, re-establishing the presence of the species in Calhoun Co. (Philips et al. 1999. Field Guide to Amphibians and Reptiles of Illinois. Illinois Natural History Survey, Champagne, Illinois. 282 pp.). One individual was captured under a board, adjacent to an equipment shed. Permits issued by the Illinois Department of Natural Resources (NH08.5174; NH08.5173). We thank the McCully Heritage Project.

PETER J. MUELLEMAN (e-mail: pjm563@truman.edu.) and **CHAD E. MONTGOMERY**, Department of Biology, Truman State University, Kirksville, Missouri 63501, USA.

SQUAMATA — SNAKES

AGKISTRODON CONTORTRIX (Copperhead). USA: MISSOURI: Grundy Co.: 200m S of NW 15th St., 1 km W of Hwy 190 (40.083292°N, 93.742302°W; WGS84). 24 May 2010. P. J. Muelleman. Verified by Chad Montgomery. Photo voucher deposited in the Dean E. Metter Memorial Collection, University of Missouri, Columbia (UMC 1843P). First county record. Partially fills a distributional gap in northern Missouri (Daniel and Edmond 2010. Atlas of Missouri Amphibians and Reptiles for 2009. <http://atlas.moherp.org/pubs/atlas09.pdf>). A 67.0 cm (SVL) adult male was captured, photographed, and released on a forested rocky hillside. A copulating pair was captured and released at this site on 29 April 2010 but no photo was taken. Collected under Missouri Department of Conservation wildlife collector's permit #14509.

PETER J. MUELLEMAN, Department of Biology, Truman State University, Kirksville, Missouri 63501, USA; e-mail: pjm563@truman.edu.

AGKISTRODON CONTORTRIX (Copperhead). USA: TENNESSEE: Robertson Co.: South of Shiloh Road, 0.2 mi SSW of junction TN 76E and Distillery Road (36.469600°N, 086.763233°W, NAD 83). 25 April 2009. Gregory T. Barrass. David H. Snyder Museum of Zoology, Austin Peay State University (APSU 18990). Verified by A. Floyd Scott. New county record (Scott and Redmond 2008. Atlas of Reptiles in Tennessee. The Center of Excellence for Field Biology, Austin Peay State University, Clarksville, Tennessee. Available from http://apsu.edu/reptatlas/ [updated 1 February 2011, accessed 20 March 2011]). Found lethargic, beneath a log pile, approximately 23m N and 15m above Sulphur Fork Creek.

GREGORY T. BARRASS and **ANDREW N. BARRASS** (e-mail: barrassa@apsu.edu), Department of Biology and The Center of Excellence for Field Biology, Austin Peay State University, Clarksville, Tennessee, USA.

CARPHOPHIS AMOENUS AMOENUS (Eastern Wormsnake). USA: GEORGIA: Dekalb Co.: Henderson Park: ~ 0.25 km from parking lot at end of Henderson Park Rd. (33.86667°N, 84.23106°W; WGS 84), elev. 306 m. 03 November 2010. Robert L. Hill. Verified by Joseph R. Mendelson. AUM AHAP-D 299–300. New county record (Jensen et al. 2008. Amphibians and Reptiles of Georgia. Univ. of Georgia Press, Athens. 575 pp.); documented previously in all counties adjacent to Dekalb. Specimen found under log at junction of two foot paths ~52 m SW of the north end of Lake Erin.

ROBERT L. HILL, Department of Research and Conservation, Atlanta Botanical Garden, Atlanta, Georgia 30309, USA; e-mail: rhill@atlantabotanicalgarden.org.

CONIOPHANES MELANOCEPHALUS (Black-headed Stripeless Snake). MÉXICO: MICHOACÁN: Municipality of Taretan: Hoyo del Aire (19.266667°N, 101.866667°W; WGS84), 887 m elev. 15 July 2006. Marco Antonio Domínguez de la Riva, Rubén Alonso Carbajal Márquez, and Eric Rivas Mercado. Verified by Luis Canseco-Márquez. Herpetological Collection, Universidad Autónoma de Aguascalientes (UAA-CV-0323). First record for Michoacán, extending its range ca. 268.54 km (air) northwest of closest known locality at Huajintlán, Morelos (Ponce-Campos and Smith 2001. Bull. Maryland Herpetol. Soc. 37:10–17). The snake was found at 2230 h crawling next to a stone wall near a small stream in subtropical dry forest.

PITUOPHIS MELANOLEUCUS MELANOLEUCUS (Northern Pinesnake). USA: ALABAMA: Hale Co.: 2.7 km E of CR 53 on CR 50 (32.954944°N, 87.482222°W; WGS84; elev. 85 m). 08 July 2006. Michael E. Welker and Scott Altnether. Verified by Craig Guyer and Robert Makowsky. University of Texas Arlington (UTA R 55651). New county record and range extension (Mount 1975. The Reptiles and Amphibians of Alabama. University of Alabama Press, Tuscaloosa. 347 pp.). DOR adult female (474 g; 134.5 cm TL) extends the known range of this species 12 km SW from the closest documented locality (AUM 23790)and brings the known range of *Pituophis m. melanoleucus* to within one county of *P. m. lodingi*.

MICHAEL E. WELKER, Ocotillo Herpetofauna and Invertebrates, 3697 Yanagisako Avenue, El Paso, Texas 79938, USA; e-mail: sustainableharvest1@gmail.com

REGINA GRAHAMII (Graham's Crayfish Snake). USA: MISSOURI: Grundy Co.: DOR, Hwy 6, 0.3 mi. W of Trenton (40.07013°N, 93.627236°W; WGS84). 24 May 2010. Chad E. Montgomery. Verified by Richard Daniel. University of Missouri-Columbia (UCM 1846P). First county record (Daniel and Edmond 2010. Atlas of Missouri Amphibians for 2009. <http://atlas.moherp.org/pubs/atlas09.pdf>). Single adult collected DOR surrounded by agricultural fields in the Thompson River floodplain. Collected under Missouri Department of Conservation wildlife collector's permit #14509 issued to PJM.

PETER J. MUELLEMAN (e-mail: pjm563@truman.edu) and **CHAD E. MONTGOMERY** (e-mail: chadmont@truman.edu), Department of Biology, Truman State University, Kirksville, Missouri 63501, USA.

RENA (= *LEPTOTYPHLOPS*) *DULCIS* (Texas Threadsnake). MÉXICO: HIDALGO: Municipality of Tasquillo: Dangu (20.50014°N, 99.25008°W; WGS84), 2230 m elev. 22 September 2008. Luis Alberto Trejo-Corona. Verified by Aurelio Ramírez-Bautista. Centro de Investigaciones Biológicas, Universidad Autónoma del Estado de Hidalgo (CIB 2185). New municipality record that reaffirms the occurrence of *R. dulcis* in Hidalgo, whose taxonomic allocation within the state had been questioned by Lemos Espinal and Smith (2007. Anfibios y Reptiles del Estado de Coahuila, México. CONABIO, México, D.F. xii + 550 pp.) and Dixon and Vaughn (2003. Texas J. Sci. 55:3–24). Most recently, Ramírez-Bautista et al. (2010. Lista Anotada de los Anfibios y Reptiles del Estado de Hidalgo, México. Universidad Autónoma del Estado de Hidalgo, y CONABIO, México, D.F. x + 104 pp.), without taxonomic comment, listed the species as occurring in two municipalities within the state (Huautla [Tamoyón] and Metztitlán [Las Casita; Presa de Apanco]). All known records to date from Hidalgo indicate that *R. dulcis* occurs in xeric to moist lowland and highland habitats ranging in elevation from about 500 to 2300 m.

This study was supported by the projects Diversidad Biológica del Estado de Hidalgo, FOMIX-CONACYT- HIDALGO 43761, 95828, and S52552-Q.

In view of its relatively small size, Panama supports one of the most diverse amphibian faunas in Central America (Jaramillo et al. 2010; Ibáñez et al. 2001; Myers and Duellman 1982). The global amphibian crisis has lead to serious population declines throughout the world, with almost all amphibian families being affected (Stuart 2004). This has been especially the case in Panama (Jaramillo et al. 2010). The major threat to amphibians is habitat loss as measured by high deforestation rates in all of Central America and other hotspots of biodiversity (Wilson and Johnson 2010; Wilson and Townsend 2010; Brooks et al. 2002). Another cause for concern is the chytrid fungal pathogen, *Batrachochytrium dendrobatidis*, which has caused mass mortalities and amphibian diversity loss in most highland amphibian populations in western Panama (Brem and Lips 2008; Crawford et al. 2010a; Lips 1999; Lips et al. 2006). However, recent amphibian species descriptions (e.g., Bolaños and Wake 2009; Crawford et al. 2010b; Köhler et al. 2007; Mendelson et al. 2008; Mendelson and Mulcahy 2010; Ryan et al. 2010; Wake et al. 2005, 2007) and continual reports on range extensions (e.g., Köhler et al. 2008) demonstrate that the amphibian inventory for Panama is still far from complete. A checklist and bibliography on the Panamanian

herpetofauna prepared by Auth (1994) listed 170 species of amphibians. Later, Young et al. (1999) published a list that contained 171 species of amphibians and additional information on provincial records and conservation status. Ibañez et al. (2001) updated the list to 176 species, and most recently Jaramillo et al. (2010) registered 199 species from Panama, including two introduced forms.

During field work from May through August 2008, we visited different sites in the Cordillera Central of western Panama in the provinces of Chiriquí, Bocas del Toro, Veraguas and the Comarca Ngöbe-Buglé, an indigenous, autonomous territory that was established in 1997 (Fig. 1). During that period, we collected 233 specimens of amphibians representing 51 species. The purpose of this paper is to report noteworthy findings among the collected material. For frogs, we present a first country record and four distributional range extensions, all of which represent first province records. We also provide new morphological and ecological information on two rarely observed salamanders.

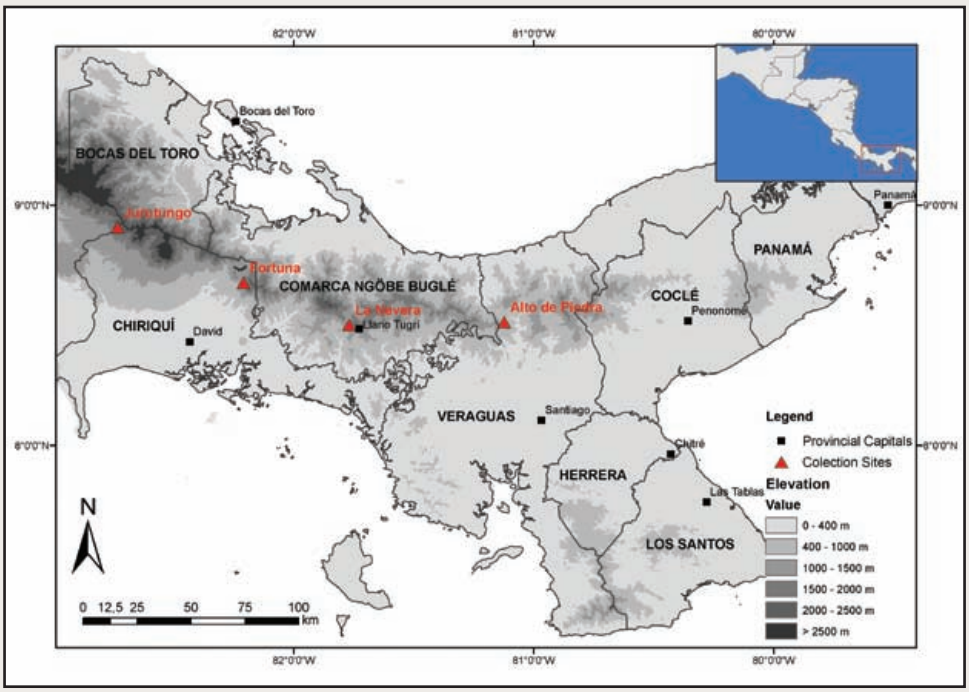

FIG. 1 Map of collection localities in western Panama denoted by red triangles, from west to east: Jurutungo, Chiriquí; Reserva Forestal La Fortuna, Chiriquí; La Nevera, Comarca Ngöbe-Buglé; Alto de Piedra, Veraguas.

All vouchers were verified by Javier Sunyer. Locality and elevational data were recorded using a GPS receiver with an integrated barometric altimeter, Garmin Etrex Summit; map datum used was WGS84. The map (Fig. 1) was created using ArcMap 10 and the shapefiles provided by the Smithonian map server at http://mapserver.stri.si.edu/. All voucher specimens are deposited in the collection of Senckenberg Forschungsinstitut und Naturmuseum (SMF). Common names were generated consulting the online database of Frost (2010), except for *Oedipina fortunensis*, which was named by translating the scientific name.

ANURA — FROGS

Hylidae

AGALYCHNIS ANNAE (Blue-Sided Leaf Frog) (Fig. 2). COMARCA NGÖBE-BUGLÉ: ca. 6.3 km W of La Nevera and 10.5 km NNW of Hato Chamí (8.5353°N, 81.8081°W), 1600 m elev. 10 May 2008. Andreas Hertz and Gunther Köhler. SMF 89791. First record for Panama, extending the known distribution ca. 230 km SE from the nearest collection site at Moravia de Chirripó, Costa Rica (Duellman 2001, who also assumed it would be found on the Caribbean slopes of western Panama). *Agalychnis annae* has suffered serious population declines and has disappeared from most of its known geographic range; it is now listed as endangered by the IUCN (Pounds et al. 2008). The only population in Costa Rica that seems to persist is found around San José (Pounds et al. 2008), thus this new record from Panama should play an important role in shaping future conservation actions.

HYLOSCIRTUS COLYMBA (La Loma Treefrog) (Fig. 3). VERAGUAS: Alto de Piedra, ca. 4 km W of Santa Fé (8.5129°N, 81.1220°W), 880 m elev. 11 July 2008. Leonard Stadler and Nadim Hamad. SMF 89794. First record for Veraguas that fills the gap between the species' nearest collection sites; Reserva Forestal Fortuna, Chiriquí; 120 km W (Lips 1999) and El Copé, Coclé; ca. 45 km E (Crawford et al. 2010). However, at both of those neighboring sites it has become extremely rare after serious declines and is listed as critically endangered by IUCN (Solis et al. 2008). Martínez and Rodríguez (1992) and Martínez et al. (1994) were the first to present inventories of the herpetofauna of the Santa Fé, Veraguas region, and mentioned finding various unidentified hylid frogs. We cannot rule out that they discovered *H. colymba* around Santa Fé, but that has become an irresolvable point because the voucher specimens were lost before they could be identified (V. Martínez, pers. com.).

Craugastoridae

CRAUGASTOR MONNICHORUM (Dunn's Robber Frog) (Fig. 4). COMARCA NGÖBE-BUGLÉ: La Nevera, Caribbean slopes, ca. 6 km NNW of Hato Chamí (8.4953°N, 81.7672°W), 1800 m elev. 14 August 2008. Andreas Hertz and Sebastian Lotzkat. SMF 89801.

FIG. 4. *Craugastor monnichorum*, La Nevera, Comarca Ngöbe-Buglé.

PHOTO BY AH

FIG. 5. *Hyalinobatrachium talamancae*, La Nevera, Comarca Ngöbe-Buglé.

First record for Comarca Ngöbe-Buglé, extending the known distribution in Panama, ca. 60 km E of the formerly easternmost collecting site at Quebrada Frank, Reserva Forestal Fortuna (Tejera and Dupuy 2003). The large female was situated ca. 30 cm above ground on a mossy liana situated in elfin woodland on the crest of a mountain ridge.

Centrolenidae

***HYALINOBATRACHIUM TALAMANCAE* (Talamanca Glass Frog)** (Fig. 5). COMARCA NGÖBE-BUGLÉ: La Nevera, Caribbean slope, ca. 6 km NNW of Hato Chamí, (8.4987°N, 81.1195°W), 1550–1600 m elev. 16 August 2008. Andreas Hertz and Sebastian Lotzkat. SMF 89798–89800. First record for Comarca Ngöbe-Buglé that fills the gap between the species' nearest collection sites at Reserva Forestal Fortuna, Chiriquí; ca. 53 km W (Kubicki et al. 2008) and Parque Nacional Altos de Campana, Panama province; ca. 195 km SE (Ibañez et al. 1996). Furthermore, this record exceeds the known elevational limit known for this species by about 484 m (Taylor 1952).

Hyalinobatrachium talamancae is often confused with *H. vireovittatum*, as both show a characteristic green mid-dorsal line and are similar in respect to their morphology, ecology, and mating calls (Kubicki 2007). However, in the latter species the mid-dorsal green line is bordered by two clearly distinguishable yellow stripes that are lacking on specimens from La Nevera. Kubicki (2007) reviewed specimens referred to as *H. vireovittatum* in the collection of the Círculo Herpetológico de Panama in 2004 and considered all to be *H. talamancae*. Moreover, in 2005 he found a population in El Valle, Coclé, that apparently is the only record of *H. vireovittatum* currently known from Panama. Nevertheless, the possibility exists that *H. vireovittatum* is a synonym of *H. talamancae* (Kubicki 2007).

Strabomantidae

***PRISTIMANTIS MORO* (La Hondura Robber Frog)** (Fig. 6). VERAGUAS: Alto de Piedra, ca. 4 km W of Santa Fé (8.5142°N, 81.1195°W), 1060 m elev. 1 August 2008. Leonard Stadler and Nadim Hamad. SMF 89796. First record for Veraguas that fills the gap between the two nearest published localities, about 360 km NW to La Hondura, San José, Costa Rica and ca.110 km SE to Valle de Antón, Coclé, Panama (Crawford et al. 2010). This

FIG. 8. *Oedipina fortunensis* with automized tail, La Fortuna, Chiriquí.

rarely observed species uses epiphytic bromeliads during daylight hours (Savage 1965, 2002). We found an amplecting pair at night on a leaf about 1.2 m above the ground in premontane wet forest. Unfortunately, the female escaped the next day, but left nine eggs inside the collection bag.

CAUDATA — SALAMANDERS

Plethodontidae

***BOLITOGLOSSA SOMBRA* (Shadowy Web-footed Salamander)** (Fig. 7). CHIRIQUÍ: Jurutungo, on the Pacific slopes of Cerro Pando, near the Costa Rican border (8.9075°N, 82.7336°W), 1850–1965 m elev. 12–13 July 2008. Andreas Hertz and Sebastian Lotzkat. SMF 89792–89793. The locality is within the known range of this recently described species (Hanken et al. 2005), but because of its rarity in collections, we here add information on morphological characteristics and ecology.

On two rainy nights, we found several of these large black salamanders, but only collected one large male and one large female. Some were found in pristine lower montane wet forest while they were walking on tree trunks; a single juvenile was inside a rotten log on the forest floor; and others were located inside a cow paddock while positioned on top of rocks. When disturbed, the salamanders were able to move astonishingly fast. Most morphometric data and tooth counts are within the documented range of variation of this species (Hanken et al. 2005). However, the two secured specimens represent the largest individuals so far reported for this species; SMF 89792, a male, has a standard length of 70 mm and SMF 89793, a female, has a standard length of 84.5 mm. The largest individuals reported before were 61.5 mm (males) and 82.7 mm (females), respectively.

***OEDIPINA FORTUNENSIS* (Fortuna Worm Salamander)** (Fig. 8). CHIRIQUÍ: Reserva Forestal Fortuna, near Río Hornito (8.677°N, 82.209°W), 1300 m elev. 18 June 2008. Andreas Hertz and Sebastian Lotzkat. SMF 89795. Our record is only the second known individual of this species reported since its description by Köhler et al. (2007), and the site is located near the type locality. The male specimen was found near the riverbank of the Río Hornito on a trail through a former citrus plantation. The salamander was on the ground and had shed its tail, probably due to our disruptive pursuit, but the extremity was retrieved for inclusion with morphological comparison to the holotype. Because of the lack of comparative statistics with the male holotype, we herein present morphometric data and tooth counts from the additional specimen; holotype values are in parentheses and abbreviations for standard measurements are those of Köhler et al. (2007): SVL 32.5 mm (33.5 mm); TL 39.0 mm, incomplete (46.5 mm); SVL/TL 0.80 (0.72); HL 5.4 mm (6.5 mm); SVL/HL 6.0 (5.2); HW 4.1 mm (3.9 mm); SVL/HW 7.9 (8.6); HHL 5.6 mm (4.3 mm); SVL/HHL 5.8 (7.8); HAW 0.9 mm (1.2 mm); SVL/HAW 36.1 (27.9); HFW 1.2 mm (1.7 mm); SVL/HFW 27.1 (19.7). A single large premaxillary tooth is distinctly offset, almost piercing the lip (same in holotype); maxillary teeth 16 (right) - 18 (left) (13-14); vomerine teeth 7 (right) - 6 (left) (7-7). The above values reasonably favor the contention that SMF 89795 is conspecific with the holotype of *O. fortunensis*.

Based on information presented by Brame (1968), the high total number of maxillary teeth (27–34) distinguishes *O. fortunensis* from other members of the subgenus *Oedopinola* in lower Central America, except *O. complex* (16–40 in males). Generally

however, adult males of *O. complex* are larger (SVL: 36.6–39 mm versus 32.5–33.5 mm in *O. fortunensis*), have a slightly broader head (SVL/HW: 8.5–9.6 versus 7.9–8.6), and more vomerine teeth (17–28 versus 13–14). Nevertheless, since both species overlap in some morphometric characters, tooth counts, geographical range, and that *O. fortunensis* presently contains only two specimens for comparison, it cannot be ruled out that *O. fortunensis* is a junior synonym of *O. complex*.

Coloration in life of SMF 89795, interpreted from Smithe (1975, 1981) (color code numbers in parentheses), was recorded as follows: Dorsal ground color of body, head, and tail Russet (34) with Warm Buff (118) mottling; dorsal surface of head and upper legs with Buff (124) blotches; lower legs and lateral surfaces of body and head Fuscous (21), merging into Sepia (119) ventrally; venter with dirty white mottling.

Acknowledgments.—Collecting and exportation permits SE/A-30-08 and SEX/A-108-08 were provided by Aleida Salazar, Yariela Hidalgo and Jorge García, Autoridad Nacional del Ambiente (ANAM), Ciudad de Panama, Panama. Querube D. Fuenmayor and Victor Martinez, Ciudad de Panama, Panama, provided valuable assistance with the acquisition of permits. An additional permit for Comarea Ngöbe-Buglé was issued by A. Montezuma (ANAM), San Félix, Panama. For field assistance we thank Smelin Abrego and Catherine O´Shea. For logistical support we thank Meike Piepenbring, Institute for Ecology, Evolution and Diversity, Goethe-Universität, Germany; Porfirio Yangüez, Río Sereno; Andrew Bennett, Lost and Found Eco Hostel; the family Peña Solis, Alto de Piedra; and the family Cáceres, Los Algarrobos. We also thank the Paul Ungerer Stiftung for financial travel support. This paper is based upon work funded to AH by the FAZIT-Stiftung, and to SL by the Studienstiftung des deutschen Volkes. Larry D. Wilson reviewed the manuscript and made welcome comments that were incorporated into the final draft.

Additional Distributional Records of Amphibians and Reptiles in Georgia, USA

Since the publication of *Amphibians and Reptiles of Georgia* (Jensen et al. 2008), numerous records of amphibians and reptiles from counties not represented in the book's species-distribution maps have been submitted to the Georgia Department of Natural Resources. These new records, as well as recent records obtained by the authors, are provided herein. Unless otherwise indicated, geo-coordinates are based on datum NAD 83. Vouchers indicated as "AHAP-D" are digital photos housed in the Auburn University Herpetological collections. Identifications were verified by Lance D. McBrayer unless indicated otherwise.

CAUDATA — SALAMANDERS

***AMBYSTOMA MACULATUM* (Spotted Salamander).** APPLING CO.: 4.5 km NW of Davis on Moody Forest Natural Area Preserve (31.930833°N, 82.283333°W). 14 March 2009. D. Stevenson and E.

Grunwald. GSU 2252. First museum voucher specimen for county. Adult found under debris in Altamaha River floodplain bottomland forest, further demonstrating that this species extends its range into the lower Coastal Plain of southeastern Georgia along this prominent hardwood corridor adjacent to the river. Coffee Co.: Flat Tub Wildlife Management Area, 10.2 km NE of Relee (31.802465°N, 82.837232°W). 07 January 2008. D. Stevenson. GSU 2249. Adult under log in hardwood forest along Ocmulgee River. First museum record for county. MONTGOMERY Co.: State Hwy. 280/30 at Oconee River, 1.3 km W of Mt. Vernon city limits (32.192261°N, 82.625411°W). 23 March 2009. D. Stevenson. GSU 2250. One of five specimens found beneath logs in hardwood forest along Oconee River. Treutlen Co.: State Hwy. 46 at Oconee River, ca. 4.0 km SSW of Barnhill (32.301508°N, 82.694247°W). 28 March 2009. D. Stevenson. GSU 2251.One of three specimens found beneath logs in hardwood forest along Oconee River.

***AMBYSTOMA OPACUM* (Marbled Salamander).** Montgomery Co.: State Hwy. 280/30 at Oconee River, 1.3 km W of Mt. Vernon city limits (32.195089°N, 82.628717°W). 23 March 2009. D. Stevenson. GSU 2253. Adult found beneath log in hardwood forest along Oconee River. Treutlen Co.: State Hwy. 46 at Oconee River, ca. 4.0 km SSW of Barnhill (32.301508°N, 82.694247°W). 28 March 2009. D. Stevenson. GSU 2254. Adult found beneath log in hardwood forest along Oconee River. Wheeler Co.: State Hwy. 46 at Oconee River, ca. 5.5 km SSW of Barnhill (32.295222°N, 82.699933°W). 28 March 2009. D. Stevenson. GSU 2255. Adult found beneath log in hardwood forest along Oconee River.

***AMBYSTOMA TIGRINUM* (Tiger Salamander).** Thomas Co.: AOR Whitney Camp Road 3.2 km S of Boston (30.762314°N, 83.785417°W). 21 December 2006. J. Young. Verified by Kenneth L. Krysko. UF 156845. Turner Co.: South side of State Hwy.107, 10.0 km E of jct. of State Hwys.107/112 (31.720478°N, 83.480383°W). 06 March 2009. D. Stevenson. GSU 2256. Larva dip-netted from borrow pit wetland adjacent to State Hwy. 107.

***AMPHIUMA MEANS* (Two-toed Amphiuma).** Wheeler Co.: 2.3 km SW of Jordan, seepage area in xeric sandhills E of Alligator Creek. (32.018342°N, 82.683306°W). 06 May 2009. D. Stevenson. GSU 2257.

***EURYCEA GUTTOLINEATA* (Three-lined Salamander).** Candler Co.: Canoochee River E of Stillmore on Stillmore-Metter Road (32.425661°N, 82.160944°W). 08 July 1976. J. Cadle. Verified by Ned Gilmore. ANSP 30811. Treutlen Co.: 6.6 km SW of Nunez, State Hwy. 297 at Ohoopee River (32.439522°N, 82.384017°W). 26 August 2009. D. Stevenson. GSU 2277. Two adults found in hardwood swamp adjacent to Ohoopee River. Twiggs Co.: Stone Creek access trail at Bond Swamp National Wildlife Refuge (32.739264°N, 83.567042°W). 27 March 2008. J. Jensen. Verified by Elizabeth McGhee. GMNH 50103. Several individuals found under logs in floodplain forest.

***EURYCEA LONGICAUDA* (Long-tailed Salamander).** Catoosa Co.: Chickamauga and Chattanooga National Military Park (34.91267°N, 85.23374°W). 26 May 2009. S. Graham and J. Jensen. Verified by Craig Guyer. AHAP-D 229. Two individuals found under logs adjacent to small stream.

***EURYCEA QUADRIDIGITATA* (Dwarf Salamander).** MONTGOMERY Co.: US Hwy. 280/State Hwy. 30 at Oconee River, 1.3 km W of Mt. Vernon city limits (32.192261°N, 82.625411°W). 23 March 2009. D. Stevenson. GSU 2279. Adult found beneath log in hardwood forest along Oconee River.

***GYRINOPHILUS PORPHYRITICUS* (Spring Salamander).** Polk Co.: Thompson Creek Gorge (33.956592°N, 85.024212°W). 03 April 2008. M. Elliott and C. Camp. Verified by Elizabeth McGhee. GMNH 50101.

***NOTOPHTHALMUS VIRIDESCENS* (Eastern Newt).** Lamar Co.: St. George's Episcopal School Campus, Milner (33.117475°N, 84.198389°W). 16 May 2007. C. Muise and T. Muise. Verified by Kenneth L. Krysko. UF 156846. MONTGOMERY Co.: US Hwy. 280/State Hwy. 30 at Oconee River, 1.3 km W of Mt. Vernon city limits (32.195089°N, 82.628717°W). 23 March 2009. D. Stevenson. GSU 2295. Adult dipnetted from pool in hardwood forest along Oconee River. Rockdale Co.: Panola Mountain State Park (33.634103°N, 84.173528°W). 12 June 2009. H. Davis. Verified by Kenneth L. Krysko. UF 156847. Treutlen Co.: State Hwy. 46 at Oconee River, ca. 4.0 km SSW of Barnhill (32.301508°N, 82.694247°W). 28 March 2009. D. Stevenson. GSU 2293. Adult dipnetted from pool in hardwood forest along Oconee River. Wayne Co.: 4.5 km NNE of Mt. Pleasant, Sansavilla Wildlife Management Area (31.456181°N, 81.656503°W). Beaver (*Castor canadensis*) wetland adjacent to NW side of Howard Road. 15 March 2009. D. Stevenson and B. Willis-Stevenson. GSU 2294.

***PSEUDOTRITON RUBER* (Red Salamander).** Telfair Co.: 1.1 km N of State Hwy. 117 at Fishing Creek (31.899402°N, 82.758076°W). 13 June 2009. D. Stevenson, W. Dopson and F. Snow. GSU 2304. Adult found in seepage area on N side of Fishing Creek.

***SIREN INTERMEDIA* (Lesser Siren).** Bacon Co.: State Hwy. 32 at Hurricane Creek, 2.0 km E of Alma (31.540425°N, 82.445125°W). 19 June 2009. D. Stevenson. GSU 2308. Adult from seepage wetland on E side of Hurricane Creek. Telfair Co.: 3.3 km ENE of Jacksonville, State Hwy. 117 at Lampkin Branch (31.816883°N, 82.944207°W). 13 July 2009. D. Stevenson. GSU 2307. Juvenile found in seepage area.

***SIREN LACERTINA* (Greater Siren).** Coffee Co.: Bay Meadows subdivision 7.7 km SW of Douglas (31.468833°N, 82.920620°W). 10 April 2009. R. Preston, Jr. GSU 2309. Found in ditch.

***URSPELERPES BRUCEI* (Patch-nosed Salamander).** Habersham Co.: Just W of Stephens county line in a tributary of Panther Creek (exact locality withheld due to rarity of species and vulnerability to over-collection). 13 August 2009. C. Camp. Verified by Elizabeth McGhee. GMNH 50121. Represents only the second county from which this recently described species has been found in Georgia.

ANURA — FROGS

***ACRIS CREPITANS* (Northern Cricket Frog).** Telfair Co.: Mopani Preserve at Ocmulgee River (31.846856°N, 82.792507°W). 28 September 2009. D. Stevenson, J. Bauder, and W. Taylor. GSU 2244. Toombs Co.: 10.7 km SE of Uvalda; Gray's Landing at Altamaha

River (31.966389°N, 82.428889°W). 10 July 2009. D. Stevenson. GSU 2243. This record further demonstrates that this species extends its range into the lower Coastal Plain of southeastern Georgia along a prominent bottomland hardwood corridor adjacent to the Altamaha River.

ANAXYRUS AMERICANUS (American Toad). Talbot Co.: AOR River Road in Big Lazar Creek Wildlife Management Area, 100 m from confluence of Lazar Creek and Flint River (32.809287°N, 84.401516°W; WGS 84). 11 June 2009. S. Graham. Verified by Craig Guyer. AHAP-D 219.

GASTROPHRYNE CAROLINENSIS (Eastern Narrow-mouthed Toad). Lamar Co.: Private residence on Eady Creek Road, Barnesville (33.126083°N, 84.138528°W). 28 August 2008. C. Muise and T. Muise. Verified by Kenneth L. Krysko. UF 156848.

HYLA CINEREA (Green Treefrog). Catoosa Co.: Small spring pond along Graysville Road (34.97809°N, 85.14338°W). 26 May 2009. J. Jensen and S. Graham. Verified by Craig Guyer. AUM 34834. Forsyth Co.: Private residence on Lillie Lane, Cumming (34.292669°N, 84.150822°W). 26 May 2009. J. Flynn. Verified by Kenneth L. Krysko. UF 156849. Murray Co.: Marsh on east side of Fox Bridge Road ca. 3.0 km N of State Hwy 225, near Holley (34.677108°N, 84.838894°W). 18 September 2007. J. Spence. Verified by Elizabeth McGhee. GMNH 50094. This species is apparently expanding its range northward, and all three county records likely represent new occurrences rather than cryptic, long-established populations.

LITHOBATES CLAMITANS (Green Frog). Catoosa Co.: Small spring pond along Graysville Road. (34.97809°N, 85.14338°W). 26 May 2009. J. Jensen and S. Graham. Verified by Craig Guyer. AUM 34835.

LITHOBATES HECKSCHERI (River Frog). McIntosh Co.: 11.1 km SW of Townsend; boat ramp at Old Fort Barrington Landing (31.470588°N, 81.605802°W). 02 August 2009. D. Stevenson and B. Willis-Stevenson. GSU 2286. Larvae found in backwater river slough.

LITHOBATES SPHENOCEPHALUS (Southern Leopard Frog). Catoosa Co.: Floodplain of Chickamauga Creek. (34.95374°N, 85.12226°W). 26 May 2009. S. Graham and J. Jensen. Verified by Craig Guyer. AHAP-D 224. Lamar Co.: St. George's Episcopal School Campus, Milner (33.117475°N, 84.198389°W). Spring 2008. C. Muise and T. Muise. Verified by Kenneth L. Krysko. UF 156850. MONTGOMERY Co.: US Hwy. 280/State Hwy. 30 at Oconee River, 1.3 km W of Mt. Vernon city limits (32.195089°N, 82.628717°W). 23 March 2009. D. Stevenson. GSU 2287.

PSEUDACRIS ORNATA (Ornate Chorus Frog). Telfair Co.: 15.8 km SW of Lumber City on State Hwy. 117 (31.861181°N, 82.8121°W). 01 March 2009. D. Stevenson and C. Jenkins. GSU 2300. Adult male captured while calling from roadside ditch. Turner Co.: South side of State Hwy.107, 10.0 km E of jct. State Hwys.107/112 (31.720478°N, 83.480383°W). 09 April 2009. D. Stevenson. GSU 2301. Larvae dip-netted from borrow pit wetland adjacent to State Hwy. 107.

SCAPHIOPUS HOLBROOKII (Eastern Spadefoot). Wheeler Co.: 3.7 air km N of Lumber City; xeric sandhills on E side of Little Ocmulgee River and N of State Hwy. 19 (31.96585°N, 82.684811°W). 02 May 2009. D. Stevenson and M. Wallace. GSU 2305. Larvae found in ephemeral, depressional wetland.

TESTUDINES — TURTLES

APALONE FEROX (Florida Softshell). Brantley Co.: DOR 3.5 km NNE Hoboken on Raybon Rock Road (31.211078°N, 82.119353°W). 12 September 2009. D. Stevenson. GSU 2259. TOOMBS Co.: Cedar Crossing Road, 0.2 km W of US Hwy. 1/State Hwy. 15/4 (31.970331°N, 82.360319°W). 06 May 2009. D. Stevenson. GSU 2261.

APALONE SPINIFERA (Spiny Softshell). Camden Co.: Satilla River opposite Big Oak (31.061694°N, 81.930829°W). 04 September 2009. D. Stevenson and G. Rogers. GSU 2268. Evans Co.: 3.3 km SW of Groveland; Canoochee River S of State Hwy. 280 (32.131444°N, 81.777190°W). 06 September 2009. D. Stevenson and B. Willis-Stevenson. GSU 2262. Jeff Davis Co.: 12.3 km NE of Hazlehurst; Altamaha River at Bullard Creek Wildlife Management Area (31.952807°N, 82.511408°W). 10 June 2009. D. Stevenson. GSU 2264. MONTGOMERY Co.: County Rte. 95 at Oconee River; Public boat launch area on Dead River Road (31.981825°N, 82.551294°W). 06 May 2009. D. Stevenson. GSU 2266. Pierce Co.: 5.3 km N of Blackshear. Alabaha River at State Hwy. 121/15 (31.350986°N, 82.237467°W). 19 June 2009. D. Stevenson. GSU 2263. Stewart Co.: Singers Pond on private plantation near Lumpkin. 19 October 2008 (31.970781°N, 84.748481°W). J. Young. Verified by Kenneth L. Krysko. UF 156852. Wheeler Co.: 2.7 km WSW of Jordan; County Rte. 197 at Alligator Creek (32.626014°N, 82.695625°W). 09 May 2009. D. Stevenson. GSU 2265.

CHELYDRA SERPENTINA (Snapping Turtle). Catoosa Co.: DOR State Hwy 2 (34.93364°N, 85.19046°W). 26 May 2009. S. Graham and J. Jensen. Verified by Craig Guyer. AHAP-D 230. Haralson Co.: Tallapoosa River, approximately 225 m S of US Hwy 78 (33.73946°N, 85.33691°W). 28 August 2009. Greg Greer and Gregory B. Pauly. Verified by Kenneth L. Krysko. UF 156853. Upson Co.: AOR Logtown Road, Yatesville (32.905661°N, 84.143372°W). 07 June 2009. C. Muise. Verified by Kenneth L. Krysko. UF 156854.

CLEMMYS GUTTATA (Spotted Turtle). Wheeler Co.: 4.1 km E of State Hwy. 19 on County Rte. 95; 0.8 km E of Mill Creek Rd. (31.959206°N, 82.612831°W). 02 May 2009. D. Stevenson and M. Wallace. GSU 2272. Adult female found DOR.

DEIROCHELYS RETICULARIA (Chicken Turtle). Wheeler Co.: 5.6 km E of State Hwy. 19 on County Rte. 95 (31.972947°N, 82.578653°W). 12 February 2009. D. Stevenson. GSU 20064. Adult female found AOR.

KINOSTERNON BAURII (Striped Mud Turtle). Laurens Co.: 10.7 km SE of Dublin; Riverbend Wildlife Management Area (32.460269°N, 82.840839°W). 26 August 2009. D. Stevenson. GSU 2282. Adult found in backwater river slough.

KINOSTERNON SUBRUBRUM (Eastern Mud Turtle). Lamar Co.: DOR US Hwy. 341, ca. 1.5 km N of Monroe County line

(32.860906°N, 84.082608°W). 14 June 2009. C. Muise. Verified by Kenneth L. Krysko. UF 156855. MONTGOMERY Co.: US Hwy. 280/State Hwy. 30 at Oconee River, 1.3 km W of Mt. Vernon city limits (32.192261°N, 82.625411°W). 23 March 2009. D. Stevenson. GSU 2283. Adult dip-netted from pool in hardwood forest along Oconee River. Taylor Co.: AOR jct. of State Hwy. 137 and State Hwy. 128 (32.666017°N, 84.104081°W). 05 May 2009. J. Jensen and S. Castleberry. Verified by Kenneth L. Krysko. UF 156856.

***PSEUDEMYS CONCINNA CONCINNA* (Eastern River Cooter)**. Jones Co.: Ocmulgee River just downstream of State Hwy. 18 bridge (32.015839°N, 83.728194°W). 26 August 2009. J. Jensen and D. Stevenson. Verified by Kenneth L. Krysko. UF 156857. Laurens Co.: Oconee River 11.3 km SE of Dublin, Riverbend Wildlife Management Area (32.454620°N, 82.837125°W). 26 August 2009. D. Stevenson. GSU 2302.

***STERNOTHERUS MINOR* (Loggerhead Musk Turtle)**. Catoosa Co.: Found on bank of Chickamauga Creek (34.95374°N, 85.12226°W). 26 May 2009. S. Graham and J. Jensen. Verified by Craig Guyer. AHAP-D 225-226.

***STERNOTHERUS ODORATUS* (Eastern Musk Turtle)**. MONTGOMERY Co.: US Hwy. 280/State Hwy. 30 at Oconee River, 1.3 km W of Mt. Vernon city limits (32.195089°N, 82.628717°W). 23 March 2009. D. Stevenson. GSU 2313. Juvenile dip-netted from pool in hardwood forest along Oconee River. Wheeler Co.: County Rte. 95 at Oconee River (31.980000°N, 82.547814°W). 04 June 2009. D. Stevenson. GSU 2312. Adult male AOR adjacent to swampy river floodplain.

***TERRAPENE CAROLINA* (Eastern Box Turtle)**. TOOMBS Co.: State Hwy. 147 at Cobb Creek (31.971648°N, 82.322175°W). 13 June 2009. D. Stevenson and B. Willis-Stevenson. GSU 2315.

***TRACHEMYS SCRIPTA* (Pond Slider)**. Lamar Co.: City Pond reservoir (33.120703°N, 84.119397°W). 06 September 2009. C. Muise, T. Muise, and A. Muise. Verified by Kenneth L. Krysko. UF 156858.

SQUAMATA — LIZARDS

***ANOLIS CAROLINENSIS* (Green Anole)**. Twiggs Co.: Stone Creek access trail at Bond Swamp National Wildlife Refuge (32.739264°N, 83.567042°W). 27 March 2008. J. Jensen. Verified by Elizabeth McGhee. GMNH 50100. Adult found in floodplain forest.

***ANOLIS SAGREI* (Brown Anole)**. Ware Co.: Laura Walker State Park (31.143475°N, 82.214586°W). 25 March 2009. J. Carter. Verified by Kenneth L. Krysko. UF 156859. Numerous individuals of this non-native species observed.

***HEMIDACTYLUS GARNOTII* (Indo-Pacific House Gecko)**. Glynn Co.: Private residence on Sunset Boulevard, Brunswick (31.216342°N, 81.471456°W). 10 September 2006. M. Butler and B. Winn. Verified by Elizabeth McGhee. GMNH 50088. First confirmed, established population of this non-native species in the state. Multiple individuals observed on house, and population has survived at least two winters (B. Winn, pers. comm.).

***HEMIDACTYLUS TURCICUS* (Mediterranean House Gecko)**. Clarke Co.: Fowler Products Company warehouse building on Collins Industrial Boulevard (33.979067°N, 83.359700°W). 14 August 1975. J. Cadle. Verified by Ned Gilmore. ANSP 30881. Evans Co.: Private residence on West Railroad Street, Claxton (32.159781°N, 81.915339°W). 09 September 2009. P. McDonald. Verified by Kenneth L. Krysko. UF 156860. Species first observed at residence approximately 15 years prior, and multiple individuals of various sizes have been seen annually since then (P. McDonald, pers. comm.). Telfair Co.: Private residence on S 2nd Avenue, McRae (32.067660°N, 82.899615°W). 12 June 2009. W. Dopson. GSU 2280. Adult female found on dwelling; five additional adult specimens observed in the vicinity.

***PLESTIODON FASCIATUS* (Common Five-lined Skink)**. Twiggs Co.: Stone Creek access trail at Bond Swamp National Wildlife Refuge (32.739264°N, 83.567042°W). 27 March 2008. J. Jensen. Verified by Elizabeth McGhee. GMNH 50099.

***PLESTIODON INEXPECTATUS* (Southeastern Five-lined Skink)**. Turner Co.: South side of State Hwy.107, 10.0 km E of jct. State Hwys.107 and 112 (31.720478°N, 83.480383°W). 09 April 2009. D. Stevenson. GSU 2298.

***SCELOPORUS UNDULATUS* (Eastern Fence Lizard)**. Lamar Co.: Private residence on Eady Creek Road, Barnesville (33.126083°N, 84.138389°W). 21 September 2008. C. Muise. Verified by Kenneth L. Krysko. UF 156861.

***SCINCELLA LATERALIS* (Little Brown Skink)**. Coffee Co.: Private residence 11.3 km WSW of Douglas (31.482556°N, 82.965020°W). 11 April 2009. F. Snow. GSU 2306. Captured in yard beneath pine straw. Lamar Co.: St. George's Episcopal School Campus, Milner (33.117475°N, 84.198389°W). 05 September 2008. C. Muise and T. Muise. Verified by Kenneth L. Krysko. UF 156903.

SQUAMATA — SNAKES

***AGKISTRODON CONTORTRIX* (Copperhead)**. Coffee Co.: New Hope Baptist Church, 1.44 km NW of Ambrose, GA (31.602934°N, 83.025112°W). 08 June 2001. D. Paulk. GSU 2248. Lamar Co.: Private residence on Eady Creek Road, Barnesville (33.126083°N, 84.138389°W). 17 May 2009. C. Muise. Verified by Kenneth L. Krysko. UF 156862. Rockdale Co.: Panola Mountain State Park (33.640667°N, 84.156194°W). 28 August 2009. C. Muise and V. Lane. Verified by Kenneth L. Krysko. UF 156935. Telfair Co.: State Hwy 117 at State Hwy 132 near Temperance (31.881148°N, 83.139010°W). 25 October 2009. Billy Kellner. GSU 2321. AOR adult. Treutlen Co.: 2.3 km SW of Barnhill; State Hwy. 46 at Oconee River Road (32.312883°N, 82.687419°W). 09 May 2009. D. Stevenson. GSU 2247.

***AGKISTRODON PISCIVORUS* (Cottonmouth)**. Bartow Co.: Green Pond at Henderson Mountain (34.269241°N, 84.918324°W). 27 July 2009. T. Morris, M. Moffett, S. Raper, and T. McCuean. Verified by Kenneth L. Krysko. UF 156863. Coffee Co.: 100 m from jct. Hwy 441 and Hwy 221, Douglas (31.490907°N, 82.851215°W). 13 May 2009. R. Preston, Jr. GSU 2245. Coweta Co.: Hutchinson Lake, Senoia (33.320069°N, 84.549319°W). July 2001. R. McCarthy.

Verified by Kenneth L. Krysko. UF 156864. McDuffie Co.: State Hwy. 17 0.8 km N of Little Brier

Creek/Warren Co. line (33.347324°N, 82.460063°W). 8 October 2009. D. Stevenson and B. Willis-Stevenson. GSU 2325. Telfair Co.: 3.3 km ENE of Jacksonville; State Hwy. 117 at Lampkin Branch (31.816883°N, 82.944207°W). 13 July 2009. D. Stevenson. GSU 2246.

CARPHOPHIS AMOENUS (Eastern Wormsnake). Catoosa Co.: Found under bark of rotten stump near Chickamauga Creek (34.95374°N, 85.12226°W). J. Jensen and S. Graham. 26 May 2009. Verified by Craig Guyer. AHAP-D 227-228.

CEMOPHORA COCCINEA (Scarlet Snake). Coffee Co.: DOR Entrance to Westwood Heights subdivision at State Hwy. 158; 3.9 km WSW of Douglas, GA (31.493121°N, 82.889002°W). 24 August 2009. R. Preston, Jr. GSU 2269. Heard Co.: Private residence in Centralhatchee (33.35333°N, 85.11000°W). 25 August 2009. M. Terry and R. McCarthy. Verified by Kenneth L. Krysko. UF 156865. Lamar Co.: Private residence on Oliver Road, Barnesville (33.050092°N, 84.099083°W). August 2009. B. Cherry. Verified by Kenneth L. Krysko. UF 156866. Pulaski Co.: Found at Sandy Hammock on bank of Ocmulgee River. (31.140401°N, 83.366332°W). 09 February 1991. F. Snow. GSU 2271. Taylor Co.: Black Creek Natural Area, ca. 1.5 km SSW of Howard (32.571356°N, 84.406653°W). 14 June 2008. N. Klaus. Verified by Kenneth L. Krysko. UF 156867. Telfair Co.: 5.2 km NW of Lumber City on State Hwy. 341/27 (31.959519°N, 82.720458°W). 2 May 2009. D. Stevenson and M. Wallace. GSU 2270.

COLUBER (= *MASTICOPHIS*) *FLAGELLUM* (Coachwhip). Bacon Co.: State Hwy. 203 N at Brown Thrasher Drive, 2.7 km SW of Appling County line (31.571311°N, 82.331094°W). 09 August 2009. D. Stevenson. GSU 2289.

CROTALUS ADAMANTEUS (Eastern Diamond-backed Rattlesnake). Cook Co.: 2.0 km SW of New Lois, W of Withlacoochee River (31.057744°N, 83.290406°W). 10 December 2008. D. Stevenson, C. Powell, M. Ravenscroft, and K. Ravenscroft. GSU 20065. MONTGOMERY Co.: Adult DOR South Old River Road at State Hwy. 221/135 (31.987425°N, 82.510467°W). 14 May 2009. D. Stevenson. GSU 2275.

CROTALUS HORRIDUS (Timber Rattlesnake). Coffee Co.: DOR jct. of Mora Road and Tractor Trail (31.420710°N, 83.007422°W). 25 August 2009. A. Safer and F. Snow. GSU 2276.

DRYMARCHON COUPERI (Eastern Indigo Snake). Cook Co.: Turkey Oak Trail at Reed Bingham State Park (31.169633°N, 83.535297°W). February 2007. C. Powell. Verified by Elizabeth McGhee. GMNH 50097.

FARANCIA ABACURA (Red-bellied Mudsnake). Jenkins Co.: State Hwy. 17 0.3 km S of Buckhead Creek, just outside Millen (32.800772°N, 81.958425°W). 21 April 1974. J. Cadle. Verified by Ned Gilmore. ANSP 30904.

HETERODON PLATIRHINOS (Eastern Hog-nosed Snake). Echols Co.: US 129/Hwy 11 E between County Rte. 10 and County Rte. 12 (30.763517°N, 83.004248°W). 15 March 2009. A. Safer and J. Safer. GSU 2281. Habersham Co.: Downtown Demorest (34.56609°N, 83.54460°W). 22 September 2008. C. Camp. Verified by Kenneth L. Krysko. UF 156868.

LAMPROPELTIS GETULA (Common Kingsnake). Jeff Davis Co.: AOR 0.4 km S of Carvers Chapel (31.689806°N, 82.804209°W). December 1991. F. Snow. GSU 2284. Wheeler Co.: 5.0 km S of Jordan on State Hwy. 19 (31.992642°N, 82.64215°W). 02 May 2009. D. Stevenson and M. Wallace. GSU 2285.

NERODIA ERYTHROGASTER (Plain-bellied Watersnake). Long Co.: 16.0 km W of Townsend (31.554132°N, 81.687387°W). 29 July 2009. D. Stevenson and K. Morris. GSU 2291. Adult found in Altamaha River floodplain swamp. Taylor Co.: Slough of Little Whitewater Creek just upstream from State Hwy. 137 bridge (32.525128°N, 84.311064°W). 25 August 2009. D. Stevenson and J. Jensen. Verified by Kenneth L. Krysko. UF 156869. Walker Co.: DOR just outside Chattanooga and Chickamauga National Military Park (34.90556°N, 85.27080°W). 26 May 2009. J. Jensen and S. Graham. Verified by Craig Guyer. AUM 34916.

NERODIA TAXISPILOTA (Brown Watersnake). Evans Co.: 3.3 km SW of Groveland; Canoochee River S of State Hwy. 280 (32.131444°N, 81.777190°W). 06 September 2009. D. Stevenson and B. Willis-Stevenson. GSU 2292.

OPHEODRYS AESTIVUS (Rough Greensnake). Telfair Co.: Adult DOR 7.9 km ENE of Jacksonville on State Hwy. 117 (31.826197°N, 82.896742°W). 04 June 2009. D. Stevenson. GSU 2297.

PANTHEROPHIS ALLEGHANIENSIS (Eastern Ratsnake). Meriwether Co.: DOR State Hwy. 109 at jct. with Jones Mill Road (33.076059°N, 84.614137°W; WGS 84). 26 November 2007. S. Graham and S. Hoss. Verified by Craig Guyer. AUM 37596.

PANTHEROPHIS GUTTATUS (Red Cornsnake). Chattooga Co.: DOR State Hwy. 157 2.7 km S of Walker Co. line (34.580504°N, 85.443711°W; WGS 84). 22 May 2009. S. Graham. Verified by Craig Guyer. AHAP-D 220.

PITUOPHIS MELANOLEUCUS (Pinesnake). Jenkins Co.: State Hwy. 121 near Burke Co. line (32.916356°N, 81.964642°W). 11 April 1976. J. Cadle. Verified by Ned Gilmore. ANSP 30934. Pickens Co.: State Hwy. 53 ca. 1.5 km SW of Ludville (34.470814°N, 84.618497°W). 04 June 2007. S. Gravette. GMNH 50098.

SISTRURUS MILIARIUS (Pygmy Rattlesnake). Atkinson Co.: Guest Mill Pond in East Flatwoods Swamp, 11.7 km SSE of Pearson (31.193483°N, 82.832963°W). 09 September 2000. D. Edwards. GSU 2311. McIntosh Co.: DOR 7.3 km SW of Townsend, Old Barrington Road at Cox Road (31.504396°N, 81.58680°W). 30 August 2009. D. Stevenson and B. Willis-Stevenson. GSU 2310.

STORERIA DEKAYI (DeKay's Brownsnake). Appling Co.: 4.5 km NW of Davis on Moody Forest Natural Area Preserve (31.930833°N, 82.283333°W). 02 March 2009. D. Stevenson and C. Jenkins. GSU 2314. Adult found under debris in Altamaha River floodplain bottomland forest. Lamar Co.: St. George's Episcopal School Campus, Milner (33.117475°N, 84.198389°W). 05 September 2008. C. Muise and T. Muise. Verified by Kenneth L.

Krysko. UF 156871. Twiggs Co.: Stone Creek access trail at Bond Swamp National Wildlife Refuge (32.739264°N, 83.567042°W). 27 March 2008. J. Jensen. GMNH 50095. Adult found under log in floodplain forest.

STORERIA OCCIPITOMACULATA (Red-bellied Snake). Jasper Co.: Private residence on State Hwy. 16 E, Monticello (33.298805°N, 83.662808°W). 09 May 2009. John B. Jensen. Verified by Kenneth L. Krysko. UF 155361. Meriwether Co.: Joe Kurz Wildlife Management Area (33.099433°N, 84.535967°W). 04 October 2008. H. Davis. Verified by Kenneth L. Krysko. UF 156872.

TANTILLA CORONATA (Southeastern Crowned Snake). Taylor Co.: Black Creek Natural Area, ca. 1.5 km SSW of Howard (32.571356°N, 84.406653°W). 13 June 2008. N. Klaus. Verified by Kenneth L. Krysko. UF 156873.

THAMNOPHIS SIRTALIS (Common Gartersnake). Coffee Co.: Old River Road (31.67977° N, 82.877807°W). 18 April 2009. A. Safer and F. Snow. GSU 2318. Tattnall Co.: Baxter Durrence Road at Mushmelon Creek, 9.2 km SSW of Glennville, by air (31.864556°N, 81.965542°W). 28 September 2009. D. Stevenson. GSU 2316. Telfair Co.: 3.7 km ESE of Jacksonville in Ocmulgee River swamp (31.800094°N, 82.942388°W). 10 June 2009. D. Blanton. GSU 2317.

VIRGINIA STRIATULA (Rough Earthsnake). Ben Hill Co.: Mobley Bluff Road boat landing on Ocmulgee River (31.775100°N, 83.007956°W). 09 June 2009. B. Hudson, C. Camp, and D. Stevenson. GSU 2319. Adult found under debris in floodplain bottomland forest.

VIRGINIA VALERIAE (Smooth Earthsnake). Coffee Co.: Walking trail 2.4 km N of South Georgia College campus between Gordon Street and Franklin Street, Douglas (31.513653°N, 82.852946°W). 30 September 2009. R. Preston, Jr. GSU 2320. Forsyth Co.: Private residence on Ivey Wood Court (34.199514°N, 84.240542°W). 24 June 2009. G. McCreary. Verified by Kenneth L. Krysko. UF 156874. White Co.: Rocky Mountain, near summit (~1200 m), E of Hwy 17 (Unicoi Gap), ca. 8.4 km N of Helen (34.798086°N, 83.729514°W). 20 September 2008. B. Hudson and C. Camp. Verified by Kenneth L. Krysko. UF 156875.

Acknowledgments.— We thank all individuals who sent us verifiable county records to further our understanding of herpetofaunal distributions in the state. Special thanks are given to the students of St. George's Episcopal School who were responsible for discovering many of the Lamar County records. We appreciate museum curators Lance McBrayer, Kenneth Krysko, and Elizabeth McGhee for verifying and accessioning specimens and photographs in a very timely manner.

Additional Geographic Distribution Records for Amphibians and Reptiles from Georgia, USA

Since the publication of *Amphibians and Reptiles of Georgia* (Jensen et al. 2008), a number of new geographic distribution records have been documented for the state, including those reported by Stevenson et al. (2009) and Jensen et al. (2011). Herein, we report 34 additional distribution records based on field collections made during 2009–2010. Geo-coordinates are based on datum NAD 83. All identifications were verified by Lance D. McBrayer.

CAUDATA — SALAMANDERS

AMBYSTOMA TALPOIDEUM (Mole Salamander). Atkinson Co.: County Rd. 38, 15.8 km SSE Willacoochee (31.203401°N, 82.999898°W). 16 March 2010. D. Stevenson and K. Stohlgren. GSU 11881. Larvae dipnetted from roadside ditch.

AMPHIUMA MEANS (Two-toed Amphiuma). Coffee Co.: Flat Tub Wildlife Management Area at Flat Tub Landing Road (31.793549°N, 82.843021°W). 14 August 2010. D. Stevenson, R. Kazmaier, and D. Riedle. GSU 11882; Jeff Davis Co.: Bullard Creek Wildlife Management Area at State Hwy. 221(31.968274°N, 82.477741°W). 3 September 2010. D. Stevenson and J. Bauder. GSU 11883; Telfair Co.: 3.3 km ENE Jacksonville. State Hwy. 117 at Lampkin Branch (31.816883°N, 82.944207°W). 22 July 2010. K.

Stohlgren and D. Stevenson. GSU 11884. Juvenile found in seepage area. Toombs Co.: State Hwy 147 at Cobb's Creek (31.974867°N, 82.323675°W). 19 August July 2010. D. Stevenson. GSU 11885.

SIREN INTERMEDIA (Lesser Siren). Ben Hill Co.: State Hwy 107/319 at Sturgeon Creek (31.773471°N, 83.054068°W). 28 July 2010. K. Stohlgren and D. Stevenson. GSU 11886.

ANURA — FROGS

ACRIS CREPITANS (Northern Cricket Frog) Jeff Davis Co.: Bullard Creek Wildlife Management Area at State Hwy. 221(31.965610°N, 82.482357°W). 3 September 2010. D. Stevenson and J. Bauder. GSU 11887

HYLA AVIVOCA (Bird-voiced Treefrog). Telfair Co.: Orianne Indigo Snake Preserve at Ocmulgee River floodplain (31.846856°N, 82.792507°W). 2 June 2010. K. Stohlgren. GSU 11888. Adult male captured while calling from bottomland forest.

LITHOBATES CLAMITANS (Green Frog). Telfair Co.: Orianne Indigo Snake Preserve at Ocmulgee River (31.846856°N, 82.792507°W). 2 May 2010. J. Bauder and K. Stohlgren. GSU 11889.

LITHOBATES HECKSCHERI (River Frog) Jeff Davis Co.: Bullard Creek Wildlife Management Area at State Hwy 221(31.965610°N, 82.482357°W). 5 September 2010. D. Stevenson and M. P.. Wallace. GSU 11890; Montgomery Co.: State Hwy 221 at the Altamaha River (31.958062°N, 82.516793°W). 10 September 2010. D. Stevenson. GSU 11891.

PSEUDACRIS FERIARUM (Upland Chorus Frog). Telfair Co.: Orianne Indigo Snake Preserve at Ocmulgee River floodplain (31.846856°N, 82.792507°W). 27 November 2009. K. Stohlgren, M. Ravenscroft and K. Ravenscroft. GSU 11892. Adult male captured while calling from bottomland forest

PSEUDACRIS ORNATA (Ornate Chorus Frog). Wheeler Co.: 5.4 km NE McRae, State Hwy 280/30 at Co. Rte. 126 (32.085298°N, 82.847111°W). 30 March 2010. W. Taylor, K. Stohlgren, and D. Stevenson. GSU 11893. Larvae dipnetted from depressional wetland.

TESTUDINES — TURTLES

APALONE FEROX (Florida Softshell). Coffee Co.: 11.7 km SW Douglas on State Hwy 135 (31.414629°N, 82.906530°W). 24 April 2010. E. Schlimm and K. Stohlgren. GSU 11894. Adult DOR, cypress wetland nearby; Tattnall Co.: State Hwy 144 at Watermelon Creek (31.928053°N, 82.003155°W). 28 September 2010. D. Stevenson. GSU 11914.

APALONE SPINIFERA (Spiny Softshell). Coffee Co.: 7.4 air km NE Relee; Flat Tub Wildlife Management Area at the Ocmulgee River (31.787834°N, 82.861011°W). 28 July 2010. D. Stevenson and K. Stohlgren. GSU 11895; Laurens Co.: 17.8 km SSE Dublin; Oconee River at Rock Springs Road boat landing (32.399131°N, 82.798492°W. 28 June 2010. D. Stevenson. GSU 11896; Ware Co.: Waycross. State Hwy 84 at the Satilla River (31.238512°N, 82.323216°W). 17 June 2010. D. Stevenson. GSU 11897.

DEIROCHELYS RETICULARIA (Chicken Turtle). Atkinson Co.: County Road 38 at Cty. Rd. 36, 14.5 km SSE of Willacoochee (31.214153°N, 83.007461°W). 16 March 2010. D. Stevenson and K. Stohlgren GSU 11898.

KINOSTERNON BAURII (Striped Mud Turtle) Jeff Davis Co.: Bullard Creek Wildlife Management Area at State Hwy 221(31.965610°N, 82.482357°W). 5 September 2010. D. Stevenson and M. P. Wallace. GSU 11899.

PSEUDEMYS CONCINNA FLORIDANA (Coastal Plain Cooter). Telfair Co.: 2.5 km SW Lumber City on State Hwy 117 (31.912864°N, 82.697977°W). 2 June 2010. K. Stohlgren. GSU 11900. Adult female AOR, man-made impoundment nearby.

STERNOTHERUS MINOR (Loggerhead Musk Turtle). Montgomery Co.: Bell's Ferry Rd. at the Oconee River (31.980202°N, 82.553902°W). 20 May 2010. D. Stevenson. GSU 11901. Toombs Co.: Gray's Landing at the Altamaha River (31.96613°N, 82.428422°W). 27 July 2010. D. Stevenson. GSU 11902.

STERNOTHERUS ODORATUS (Eastern Musk Turtle). Jeff Davis Co.: Bullard Creek Wildlife Management Area at State Hwy 221(31.968274°N, 82.477741°W). 5 September 2010. D. Stevenson and M. P. Wallace. GSU 11915–16.

SQUAMATA — LIZARDS

PLESTIODON FASCIATUS (Common Five-lined Skink). Jeff Davis Co.: Bullard Creek Wildlife Management Area at State Hwy 221(31.965610°N, 82.482357°W). 10 September 2010. D. Stevenson. GSU 11903.

SQUAMATA — SNAKES

AGKISTRODON PISCIVORUS (Cottonmouth). Toombs Co.: Providence Church Rd. at Bell's Mill Creek (31.954659°N, 82.244034°W). 24 September 2010. D. Stevenson. GSU 11904.

CROTALUS ADAMANTEUS (Eastern Diamond-backed Rattlesnake). Atkinson Co.: County Rd. 38, 7.0 km S Willacoochee (31.279601°N, 83.026359°W). 16 March 2010. D. Stevenson and K. Stohlgren. GSU 11905. Adult found at Gopher Tortoise (*Gopherus polyphemus*) burrow in xeric sandhill.

CROTALUS HORRIDUS (Timber Rattlesnake). Decatur Co: State Hwy 253, 16.8 km NNE Bainbridge (31.04973°N, 84.52710°W). 25 July 2010. Juvenile found DOR. E. Schlimm and K. Stohlgren. GSU 11906.

FARANCIA ERYTROGRAMMA (Rainbow Snake). Tattnall Co.: State Hwy 178 at the Ohoopee River, 18.0 air km W Glennville (31.922805°N, 82.118758°W).1 June 2010. D. Stevenson. GSU 11907. Adult female found in shallow water of the Ohoopee River at 1330 h. It was attempting to eat an American Eel (*Anguilla rostrata*).

NERODIA ERYTHROGASTER (Plain-bellied Watersnake). Montgomery Co.: Bell's Ferry Rd. at the Oconee River (31.980202°N, 82.553902°W). 14 July 2010. D. Stevenson. GSU 11908; Telfair

ART IN HERPETOLOGY

SUBJECT: California red-legged frog (*Rana draytonii*) SIZE: Painted area is approx. 8" x 9" on 11" x 14" paper

Cindy Hitchcock earned a BA in Fine Arts emphasizing in drawing and painting and a MS in Biology, emphasizing herpetology and amphibian decline. Cindy was formerly a graphic designer for Pepsi Cola Company and Lennox China, but later worked as a biologist for US Geological Survey and Aspen Environmental Group in Southern California. She now resides in Reseda, California with her husband (herpetologist Robert Espinoza) and two children (Max and Olivia). For archival prints of the featured paintings or for biological illustration services please contact cindyhitchcock@yahoo.com.

NATURAL HISTORY NOTES

CAUDATA — SALAMANDERS

***BOLITOGLOSSA PLATYDACTYLA* (Broad-footed Mushroom-tongued Salamander). MAXIMUM ELEVATION.** *Bolitoglossa platydactyla* is known to inhabit an elevational distribution of 0–1300 m (Duellman 1999. Patterns of Distribution of Amphibians. A Global Perspective. The Johns Hopkins University Press. Baltimore and London. 633 pp.). Within the state of Hidalgo, México, the maximum elevation previously known for *B. platydactyla* was 148 m in rainforest (Hernández-Salinas et al. 2008. Herpetol. Rev. 39:231). On 12 February 2010, an adult *B. platydactyla* was captured under a stone in the cloud forest in the municipality of San Bartolo Tutotepec (20.40442°N, 98.22689°W; WGS 84) at an elevation of 1510 m. This record provides information on the potential elevation of this species, and is the first record of *B. platydactyla* for cloud-forest habitat in Mexico.

We thank Ch. Berriozabal Islas for logistical assistance. We also thank the projects SEP PROMEP 1103.5/03/1130, CONACYT-S 52552-Q and FOMIX-CONACYT- 95828.

***NOTOPHTHALMUS VIRIDESCENS* (Eastern Newt). NECROPHILIA AND CANNIBALISM.** On 22 March 2010, in a wetland located in Pickens Co., South Carolina, USA, we observed a pair of adult *Notophthalmus viridescens* engaged in what appeared to be amplexus and a third adult *N. viridescens* attempting interference of the mating pair. Upon closer examination, we saw that a male *N. viridescens* was mounting a decapitated female *N. viridescens*. The third *N. viridescens* was feeding on the exposed soft tissue of the decapitated female *N. viridescens*. We do not know if the decapitation occurred prior to amplexus or after. *Notophthalmus viridescens* are opportunistic feeders and the cannibalism of larvae by adults has been documented (Burton 1977. Copeia 1977:139–143). This coincidence of necrophilia and cannibalism of an adult *N. viridescens* appears to be unique.

Notophthalmus viridescens amplexus can last for up to three hours, and thus represents a substantial energetic investment in reproduction (Verrell 1985. Behaviour 94:244–253). Trauth et al. (2000. J. Arkansas Acad. Sci. 54:154–156) posited that by engaging in or continuing amplexus with a dead female, a male amphibian may diminish his reproductive output due to increased energetic costs and wasting gametes.

Amplexus between live male and dead female anurans has been documented for several species (Mollov et al. 2010. Biharean Biol. 4:121–125; Trauth et al. 2000, *op. cit.*) and death of female anurans as a result of mating activities has been observed for Wood Frogs, *Lithobates sylvaticus* (Trauth et al. 2000, *op. cit.*). Amplexus may represent a time of increased female vulnerability that can lead to mortality.

We extend our gratitude to the South Carolina State Parks, Upstate Forever, South Carolina Department of Natural Resources, and John Garten for assistance in locating wetlands. We thank the Clemson students who participated in field work. Funding was provided by the Environmental Protection Agency Region 4 WPDG. Research was approved by Clemson University IACUC (AUP2009-103).

***PLETHODON CINEREUS* (Eastern Red-backed Salamander). WILDFIRE SURVIVAL.** *Plethodon cinereus* is an entirely terrestrial plethodontid salamander at the northeastern extreme of its natural distribution in Nova Scotia, Canada (Petranka 1998. Salamanders of the United States and Canada. Smithsonian Institution Press, Washington, D.C. 587 pp.). On 30 April 2009, a wildfire of anthropogenic origin was ignited on the periphery of Halifax, Nova Scotia, Canada (44.60147°N, 63.59264°W), fueled by downed trees remaining from a 2003 hurricane. This stand-replacing fire ultimately consumed 800 ha of Acadian forest including above-ground vegetation, woody debris, and the organic soil layer, removing critical salamander habitat. *Plethodon cinereus* was the most commonly observed terrestrial amphibian in the study area before the fire (pers. obs.). Most studies of fire effects on herpetofauna address low-severity burns (Dechant 2007. Low-Intensity Prescribed Fire does not Affect Salamanders in an Oak-Hickory Woodland. M.Sc. Thesis, Univ. Michigan, Ann Arbor. 29 pp.), and few address the effects of stand-replacement wildfire (Bury 2004. Cons. Biol. 18:968–975) due to difficulties in measurement, frequency, and experimental manipulation. A single *P. cinereus* was observed under rocky debris on an unburned rock outcrop (44.58486°N, 63.55519°W) on 9 May 2009, 302 m from the nearest unburned area. Based on their small territories (0.16–0.33 m^2) (Petranka 1998, *op. cit.*) and dispersal distances of less than 2 m per year (Ousterhout and Liebgold 2010. Herpetologica 66:269–275), it is unlikely that *P. cinereus* migrated across the burned zone in the nine days following the fire. Taub (1961. Ecology 42:681–698) demonstrated a large reservoir of *P. cinereus* in the soil and some individuals never moved to the surface. *Plethodon cinereus* have limited burrowing abilities, restricting them to soft substrates such as leaf litter (Heatwole 1960. Ecology 41:661–668). *Plethodon cinereus* residing in the leaf litter and organic soil layer or under woody debris at this location probably perished in the fire, but individuals could potentially have

survived in unburned rock piles which provided refuge from combustion and extreme temperatures. Multiple searches of the surrounding area and monitoring of artificial cover objects over the next four months did not result in any further observations of *P. cinereus* on burned soils. This observation indicates that 1) wildfire adversely affects *P. cinereus* populations immediately following the fire; and 2) amphibian recolonization of extensively burned landscapes may occur from unburned refugia within the fire zone.

RONALD W. RUSSELL, Department of Biology, Saint Mary's University, 923 Robie St., Halifax, Nova Scotia, Canada B3H 3C3; e-mail: ron.russell@smu.ca.

***SIREN LACERTINA* (Greater Siren). DIET.** On 20 Oct 2010 a dead *Siren lacertina* was found in a minnow trap in Southern Landing, a 1.4-acre constructed wetland on the Florida Southern College campus in Lakeland, Florida, USA. Once collected from the trap, the siren was placed in tap water and kept overnight in the laboratory at 10° C until it was dissected on 21 Oct 2010. Upon dissection, a *Nerodia taxispilota* (Brown Water Snake), in the later stages of digestion, was recovered from the siren's small intestine. The *N. taxispilota* was partially intact (i.e., the bones and scales were poorly digested) and had a TL of ca. 17 cm. In addition to the snake, the siren had consumed large amounts of muddy vegetation that contained snails, fingernail clams, amphipods, and chironomid larvae. The siren was 483 mm SVL, 650 mm TL, and its mouth had a vertical gape of ca. 12 mm with a horizontal opening of ca. 17 mm. The Greater Siren has been known to consume small fish (Hanlin 1978. Copeia 1978:358–360) and salamanders (Luhring 2007. Herpetol. Rev. 38:317), however this is the first account of consumption of a reptile by *S. lacertina*.

ANURA — FROGS

***HYLA ARENICOLOR* (Canyon Tree Frog). MISSING LIMBS.** Severe deformities have been reported in several species of amphibians, in which supernumerary and ectromelia are the most common (Blaustein and Johnson 2003. Front. Ecol. Environ. 1:87–94). Here, I report an apparently high occurrence of *Hyla arenicolor* with completely missing hindlimbs.

On two field trips (9 and 22 Oct 2004) to the Sierra de Nanchititla, State of Mexico, Mexico (18.8241944°N, 100.42772°W; elev. 1435 m), I sampled a total of 12 adult and 40 tadpole *H. arenicolor*. Individuals were collected next to Nanchititla Falls in two different temporary ponds. Three adults had completely missing hindlimbs (ectromelia). Tadpoles did not show any sign of deformity.

Potential sources of missing limbs include both abiotic and biotic factors (Blaustein and Johnson 2003. Sci. Amer. 288(2):60–65). A detailed study, including frequencies of deformities in this and other species, and the sources of such deformities in this relatively isolated and protected area are needed.

I thank Carlos Pérez, Miguel Medina, Wenceslao González, and Amanda Plata for field assistance and Lourdes Ruiz for reading a draft of this note.

OSWALDO HERNÁNDEZ-GALLEGOS, Centro de Investigación en Recursos Bióticos, Facultad de Ciencias, Universidad Autónoma del Estado de México, Instituto Literario 100, Toluca Centro, Estado de México, México, C.P. 50000; e-mail: ohg@uaemex.mx.

***HYLARANA MALABARICA* (Fungoid Frog). PREDATION.** On 7 August 2009 at 0030 h, we located a breeding congregation of *Hylarana malabarica* in a temporary water pool surrounded by *Ipomoea carnea* in Judia Farm, Keonjhar district, Odisha, India (21.949475°N, 84.3600861°E; 400 m elev.; WGS 84). As we photographed a calling male sitting on a stump, the frog jumped into water and was immediately caught by a giant water bug (*Belostoma indicum*) (Fig. 1). The frog was grasped laterally near the groin with a tight grip of its legs, uttered a distress, and died within 15 minutes of capture. *Belostoma indicum* in its nymphal stage is known to kill subadult *Hoplobatrachus tigerinus* by strangulation (Mitra 1975. J. Bombay. Nat. Hist Soc. 72[2]:599–600). However, during our observation the frog was killed while the *B. indicum* had a tight grip on its groin region. *Hylarana malabarica* is distributed in Western Ghats, Eastern Ghats, and Peninsular India and it lives in tree holes, below leaf litter, under boulders, and in caves (Dutta et al. 2009. Amphibians and Reptiles of Similipal Biosphere Reserve. Regional Plant Resource Centre, Bhubaneswar, Orissa, India. 174 pp.). During the monsoon season, breeding congregations are found near ponds and temporary water pools syntopic with B. indicum.

Although predation of amphibians by arthropods has been reported by many workers (e.g., Barej et al. 2009. Herpetol. Notes 2:137–139; Forti et al. 2007. Braz. J. Biol. 67:583–584; Figueiredo-de-Andrade et al. 2010. Herpetol. Notes 3:53–54), this is the first record of predation of *H. malabarica* by *B. indicum* in nature.

COLOR REPRODUCTION SUPPORTED BY THE THOMAS BEAUVAIS FUND

***LEPTOBRACHIUM HASSELTII* (Hasselt's Litter Toad). ANTIPREDATOR BEHAVIOR.** *Leptobrachium hasseltii* is a megophryid toad occurring in the southern part of Sumatra, Java, Bali, and

COLOR REPRODUCTION SUPPORTED BY THE THOMAS BEAUVAIS FUND

FIG. 1. Antipredator behavior exhibited by *Leptobrachium hasseltii*—posterior body elevation, hind limbs outstretched, and head flexed downward.

several adjacent islands of Indonesia (Hamidy and Matsui 2010. Zootaxa 2395:24–44; Iskandar 1998. The Amphibians of Java and Bali. Research and Development Centre for Biology-LIPI, Bogor. xix + 117 pp.). The antipredator behavior of *Leptobrachium* has been reported for *L. smithi* from Thailand (Chuaynkern et al. 2007. Herpetol. Rev. 38:323–324). The behavior in that species includes arching of the back with its head elevating ca. 90°, and the bulging of eyes with prominent display of the contrasting orange and black eye colors (Chuaynkern et al. 2007, *op. cit.*). Here, we observed a different pattern of antipredator behavior of *Leptobrachium*. We collected a female *L. hasseltii* from Banyuwindu, Ungaran, Central Java (2.442°N, 103.242°E, 111 m elev.) on 29 July 2010. As we photographed the specimen, it performed an antipredator behavior by elevating the posterior part of the body, outstretching the hind limbs, and flexing its head downward (Fig. 1). This type of antipredator behavior has been reported for several bufonids including *Bufo bufo* (Beebee 1985. Frogs and Toads. Whittet Books, London. 121 pp.), *Epidalea clamaita* (Noble 1931. The Biology of the Amphibia. Dover Publications Inc., New York. 577 pp.), and *Rhinella marina* (Tyler 1976. Frogs. William Collins Ltd., Sydney. 256 pp.), as well as a microhylid *Phrynomantis bifasciatus* (Duellman and Trueb 1986. Biology of Amphibians. The John Hopkins Univ. Press, Baltimore. 670 pp.), and is thought to increase apparent body size. The different antipredator behaviors exhibited by *L. smithi* and *L. hasseltii* might be related to different predator pressures, although similar predators are present in their respective ranges. Because species of this genus are characterized by their disproportionately large head (Inger and Stuebing 1997. A Field Guide to the Frogs of Borneo. Natural History Publications Sdn. Bhd., Kota Kinabalu. ix + 205 pp.), behavior seen in *L. hasseltii* seems to be effective, while the "Unken-reflex" (Noble 1931, *op. cit.*) displayed by *L. smithi* is otherwise uncommon in species of this genus. Bright ventral coloration and potent skin secretions are unknown in this group.

The specimen reported here is deposited in the Graduate School of Human and Environmental Studies, Kyoto University (KUHE 44305). Field work was financed by Monbukagakusho to AH for his doctoral scholarship.

AMIR HAMIDY (e-mail: amir.hamidy@at5.ecs.kyoto-u.ac.jp) and **MASAFUMI MATSUI** (e-mail: fumi@zoo.zool.kyoto-u.ac.jp), Graduate School of Human and Environmental Studies, Kyoto University, Japan.

***LEPTODACTYLUS BUFONIUS* (Vizcacheras' White-lipped Frog). SPAWNING BEHAVIOR.** *Leptodactylus bufonius* is a typical frog from the arid Chaco, and is included in the *L. fuscus* group (Heyer 1978. Bull. Los Angeles Co. Mus. Nat. Hist. 29:1–85). It occurs in southern Bolivia, northern Argentina, Paraguay, and Central Brazil (Mato Grosso do Sul state) (Frost 2010. Amphibian Species of the World. Electronic database accessible at <http://research.amnh.org/vz/herpetology/amphibia/>, American Museum of Natural History, New York). Species in this group exhibit an intermediate reproductive mode, from the aquatic to terrestrial, with terrestrial clutches and aquatic tadpoles. Males construct subterranean chambers close to streams or ponds, and eggs embedded in foam nests are deposited inside the chambers. Subsequent to rains or floods, tadpoles complete development in the water (Heyer 1969. Evolution 23:421–428). Studies on the reproductive biology of *L. bufonius* throughout its geographic distribution are scarce (Crump 1995. Herpetol. Rev. 26:97–98; Reading and Jofré 2003. Amphibia-Reptilia 24:415–427) and nonexistent for Brazilian populations. Herein, we describe some aspects of the spawning behavior of *L. bufonius* in a temporary pond (21.7°S, 57.717°W), in the municipality of Porto Murtinho, Mato Grosso do Sul state, western Brazil. The study site is located in the southern Pantanal, the only Brazilian region under the influence of the Chaco biome, where annual floods are common in the summer (Prado et al. 1992. *In* Furley et al. [eds.], Nature and Dynamics of Forest-Savanna Boundaries, pp. 451–470. Chapman and Hall, London; Silva and Abdon 1998. Pesq. Agropec. Bras. 33:1703–1711). Climate is "Aw" type, according to Köppen's classification, with a hot and wet summer (Oct–Apr) and a dry and cold winter (May–Sep).

On 3 Dec 2009, 2230 h, we observed a pair of *L. bufonius* in amplexus inside a chamber, but spawning had not started. At 2232 h, another male entered the same chamber and immediately they started spawning. At 2300 h, with the foam nest already formed, the female (Coleção Zoológica de Referência da Universidade Federal de Mato Grosso do Sul – ZUFMS -CH593) left the chamber. Both males remained inside the chamber until 2344 h, when one of the males left the chamber (ZUFMS-CH594), followed by the other male at 2355 h (ZUFMS-CH595). On 6 Dec 2009 we observed another male being followed by a female and both entered the chamber at 2120 h. After five minutes, the male left the chamber and remained motionless for 35 minutes, ca. 10 cm from the chamber entrance. During this period, the female remained with her head out of the chamber. At 2205 h, both returned to the chamber and amplexed. After 20 minutes they started spawning. At 2245 h, another female (ZUFMS-CH598) approached the chamber and, at 2307 h joined the pair that was spawning. After seven minutes, this second female left. Thirty minutes later, another male approached and entered in the chamber. The three individuals (two males and one female) remained inside the chamber for almost 40 minutes (until 0028 h), when the female left. At 0047 h one male (ZUFMS-CH599) left and at 0100 h the other male (ZUFMS-CH600) also left the chamber. We were able to recognize males and females because of the presence/absence of vocal sacs; behavioral observation was possible through the chamber entrance. Observations of chambers

containing more than a male and female have been reported for *L. bufonius* (Philibosian et al. 1974. Herpetologica 30:381–386; Pisanó et al. 1993. Rev. Fr. Aquariol. 19:125–126; Reading and Jofré 2003, *op. cit.*). Philibosian et al. (1974, *op. cit.*) suggested that *L. bufonius* may exhibit polyandrous behavior or males may use chambers of other males. The second scenario seems more plausible for the population studied in Argentina by Reading and Jofré (2003, *op. cit.*). These authors stated that the available evidence did not support polyandry. Given that *L. bufonius* individuals occur in high densities at our study site, and that the region is subjected to floods which may shorten the reproductive period because of lack of suitable sites to construct the chambers, we suggest that the occurrence of multimale and perhaps multifemale spawning behavior seems plausible for this population. Polyandry has rarely been reported for South American frogs (Prado and Haddad 2003. J. Herpetol. 37:354–362; Prado et al. 2006. Herpetol. Rev. 37:206–207). In species with external fertilization, as most anurans, one of the ways to increase fertilization success is increasing quantity of sperm released (Gross 1985. Nature 313:47–48). Thus, selection may favor males with larger testes (Prado and Haddad 2003, *op. cit.*). Studies on the reproductive effort (gonad mass relative to body mass) of *L. bufonius* males, as well as studies addressing offspring paternity, are needed to help understand the behaviors described herein.

We are grateful to Conselho Nacional de Desenvolvimento Científico e Tecnológico, CNPq (proc. # 470484/2007-1), for financial support and to Oswaldo Ovelar (Seu Bala), who permitted access to the site. ***LIMNONECTES PALAVANENSIS* (Smooth Guardian Frog). ALTITUDE.** *Limnonectes palavanensis* is a small (to 40 mm SVL) raniform anuran with conspicuous tympanum and supratympanic folds, smooth reddish to chocolate brown on top of the head and dorsum except for a distinctive inverted V-shaped ridge between the shoulders and two unbroken folds from behind the eyes to the lower back, several posterior dorsolateral dark spots, immaculate orange yellow venter, and half-webbed toes with faintly dilated tips (Inger 2005. The Systematics and Zoogeography of the Amphibia of Borneo. Natural History Publications [Borneo] Sdn. Bhd. Kota Kinabalu. 402 pp.; Malkmus et al. 2002. Amphibians and Reptiles of Mount Kinabalu [North Borneo]. A.R.G. Gantner Verlag K.G. Ruggell. 424 pp.). *Limnonectes palavanensis* occurs in Palawan of the Philippines, and Borneo (Sabah and Sarawak of Malaysia, Brunei Darussalam, and Kalimantan of Indonesia) (Das 2007. A Pocket Guide: Amphibians and Reptiles of Brunei. Natural History Publications [Borneo] Sdn. Bhd. Kota Kinabalu. viii + 200 pp.; Inger 2005, *op. cit.*; Inger 2007. Systematics and Zoogeography of Philippine Amphibia. Natural History Publications [Borneo] Sdn. Bhd. Kota Kinabalu. vi + 370 pp.). Previous publications reported the altitudinal range for the species to be from near sea level to 1300 m elev. (Inger and Stuebing 2005. A Field Guide to the Frogs of Borneo, 2nd ed. Natural History Publications [Borneo] Sdn. Bhd. Kota Kinabalu. viii + 201 pp.; Malkmus et al. 2002, *op. cit.*). Herein we report a new altitude limit for *L. palavanensis*.

On 11 Dec 2008, between 1900 and 2200 h, an adult *L. palavanensis* (26 mm SVL, 1.7 g) was sampled via opportunistic examination at Geludu Trail on Geludu Hill (6°N, 116.5375°E; 1502 m elev.), Bundu Tuhan, Ranau District, West Coast Division, Sabah, Bornean Malaysia. The male anuran was found on the forest floor among dead leaves, and was not guarding eggs or carrying tadpoles. Air temperature was 16.2°C, and relative humidity was 88.1%. Geludu Hill is densely forested with elevation of 1200–1550 m. The hill houses other anuran species associated with forest floor such as *Ansonia longidigita*, *Leptobrachella baluensis*, *Leptobrachium montanum*, *Leptolalax dringi*, and *Chaperina fusca*, as well as with primary forest: *Philautus aurantium*, *P. bunitus*, *P. petersi*, and *Rhacophorus angulirostris*. The locality represents an extension of habitat for *L. palavanensis* from submontane to the montane zone. The specimen (HEP00913) was deposited in BORNEENSIS, the Bornean reference collection of the Institute for Tropical Biology and Conservation, Universiti Malaysia Sabah. On the same night, an additional *L. palavanensis* was sampled at Geludu Hill at 1478 m elev. (HEP00912: SVL 37 mm, mass 5.1 g).

We are grateful to Agnes James Lintanga for permission to sample on her land on Geludu Hill, and for assistance in the field. We thank Haleluyah Retreat Centre for lodgings support. We also thank the Institute for Tropical Biology and Conservation, Universiti Malaysia Sabah for support.

***LITHOBATES AREOLATUS CIRCULOSUS* (Northern Crawfish Frog). WINTERKILL.** Herein we report the first documented instance of winterkill in *Lithobates areolatus*, a state endangered species in Indiana and a species thought to be threatened throughout its range (Parris and Redmer 2005. *In* Lannoo [ed.] Amphibian Declines: Conservation Status of United States Species, pp. 526–528. Univ. California Press, Berkeley, California.). Our study population is located at the Hillenbrand Fish and Wildlife Area, in Greene Co. in southwestern Indiana (Lannoo et al. 2009. Diversity 1:118–132). This population is about 40 km SSE of the northernmost known extant population in Indiana, and probably at this point in time, the species. At this latitude, Crawfish Frogs overwinter obligately in burrows—one frog per burrow—excavated by crayfish (*Cambarus diogenes*, *C. polychromatus*, or *Fallicambarus fodiens*; Heemeyer and Lannoo 2010. Herpetol. Rev. 41:168–179). These burrows are small-bore—about the width of the frog—and long, extending a meter, perhaps more, down into the water table (Thompson 1915. Occ. Pap. Mus. Zool. Univ. Michigan 9:1–7). Crawfish Frogs spend the

FIG. 1. Flooded Crawfish Frog burrow; feeding platform is the muddy area immediately to the left and below the entrance in this photograph. Photo taken on 14 October 2009, after several days of heavy rains. Burrow entrance is about 8 cm in diameter.

FIG. 2. A) A thin incomplete ice cap covering the burrow of Crawfish Frog 9. Burrow entrance about 14 cm across. B) A magnified view of Frog 538 (headwidth 40 mm) partially submerged sitting in the water of her burrow after the ice cap had been broken and cleared. Distance from ice cap to the water was approximately 10 cm. Photos taken on 10 Dec 2009.

winter in or near the water at the bottom of their burrow, either partially submerged with their nostrils above the water or completely submerged with occasional emergence (especially under warm conditions). Crawfish Frogs will drown if submerged for extended periods of time (Heemeyer and Lannoo 2010, *op. cit.*).

During the winter of 2009–2010 we monitored 14 Crawfish Frogs on a weekly basis until 1 March, when we resumed daily monitoring. We observed frogs at the entrance or out of their burrows during every month of the winter. Temperature and precipitation data were recorded every 10 min throughout the winter using a HoboWare weather station located at a secure site 4.4 km NW of our study area. October 2009 was unusually wet (114 mm of rain, 28.7 mm above the 10-yr monthly average), with heavy rains coming on the 8th, 9th, and 14th. These rains raised the water table to the soil surface and inundated Crawfish Frog burrows (Fig. 1). For much of the winter (December was also wet) the water table remained near the soil surface. Throughout the winter we noticed a general pattern of rain leading a cold front, which led to burrow inundation with ice formation over the burrow entrance, followed by a fast or slow percolation of water out of burrows. This drainage created an air pocket between the ice and the water surface (Fig. 2). Burrows did not drain evenly in the clay-capped mine spoil soils of our study site (Lannoo et al. 2009, *op. cit.*). Later warming produced thawing and open burrow entrances. At no time during the winter was there enough persistent snow to provide insulation to retain ground heat.

January and February were cold, with a minimum recorded temperature of –20.4°C. On 21–22 February it rained 2.6 cm, and from 23–25 February a cold snap froze the entrances to many burrows, and in particular the burrow of Crawfish Frog number 9. Frog 9 was a large male (119 mm SUL, 152 g minus the transmitter [3.8 g]) whose burrow was situated on a south-facing hillside, in deep clay, in a pocket shaded by several large clusters of Big Bluestem (*Andropogon gerardii*). As a consequence of being sheltered and in thick clay, the ice at the entrance to this burrow was thick (centimeters), the water in the burrow did not drain to form an air pocket, and the ice over the burrow did not thaw quickly. When it did, on 7 March, we saw Frog 9 below the water level, something that is not unusual and typically not cause for alarm. On 9 March we realized Frog 9 had not moved and JLH extracted him. The carcass was fresh, and necropsy followed by consultation with Alan Pessier, D.V.M., suggested death by either drowning or asphyxiation. Among all (14) burrows surveyed, Frog 9's burrow had the thickest ice, was the last to thaw, and had the highest water table relative to the ground surface.

Frog 9 was the only monitored frog to die over the winter, and over the course of this study (16 months to date) has been only the second Crawfish Frog in a burrow to die (Engbrecht and Heemeyer 2010. Herpetol. Rev. 41:197). In the absence of heavy fall rains, we expect the winter water table to be close to or below the frost line (76 cm), and for Crawfish Frogs sheltered (water has a higher thermal inertia than air) in the water at the bottom of crayfish burrows to be relatively protected from the several potential consequences of freezing temperatures.

We thank Alan Pessier for the consultation following our necropsy.

JENNIFER L. HEEMEYER (e-mail: jheemeyer@indstate.edu) and **MICHAEL J. LANNOO** (e-mail: mlannoo@iupui.edu), Indiana University School of Medicine-TH, Rm. 135, Holmstedt Hall-ISU, Terre Haute, Indiana 47809-9989, USA.

***LITHOBATES SYLVATICUS* (Wood Frog). PREDATION.** *Lithobates sylvaticus* are prey to mammals, large birds, snakes, fish, leeches, and salamander larvae (Baldwin et al. 2007. Herpetol. Rev. 38:194–195; Dorcas and Gibbons 2008. Frogs and Toads of the Southeast. Univ. Georgia Press, Athens, Georgia. 238 pp.). *Lithobates sylvaticus* eggs and tadpoles may also be an important seasonal prey item for *Notophthalmus viridescens*. During March–April 2010, *N. viridescens* was observed actively feeding on *L. sylvaticus* eggs and tadpoles at five separate temporary wetlands located within Oconee and Pickens counties in South Carolina. *Notophthalmus viridescens* would either approach egg masses from the sides or from underneath and consume eggs from these areas. In all cases, a minimum of three *N. viridescens* at a time were observed actively feeding on *L. sylvaticus* eggs. We also observed the consumption of *L. sylvaticus* tadpoles by *N. viridescens*. However, *L. sylvaticus* tadpoles appeared to avoid predation by purposefully positioning themselves on top of the remaining egg masses (i.e., tadpoles were observed swimming from other areas of the wetland to the top of the egg masses then remained there with minimal body movement for at least the duration of our observations). This observation may represent an example of active predator avoidance behavior by *L. sylvaticus* tadpoles. *Notophthalmus viridescens* were not observed in these wetlands prior to the *L. sylvaticus* breeding season and few were observed in these wetlands after *L. sylvaticus* eggs and tadpoles were no longer present. This pattern suggests that *N. viridescens* may seasonally occupy temporary wetlands following *L. sylvaticus* reproduction.

We extend our gratitude to the South Carolina State Parks, Upstate Forever, South Carolina Department of Natural Resources, and John Garten for assistance in locating wetlands. We thank the Clemson students who participated in field work. Funding was provided by the Environmental Protection Agency Region 4 WPDG. Research was approved by Clemson University IACUC (AUP2009-103).

AMBER L. PITT (e-mail: apitt@clemson.edu), **CORA M. ALLARD, JOANNA E. HAWLEY, ROBERT F. BALDWIN**, and **BRYAN L. BROWN**, Department of Forestry and Natural Resources, Clemson University, Lehotsky Hall, Clemson South Carolina 29634, USA.

***RHINELLA POMBALI* (Pombal's Toad). PREDATION.** The capture of animals by drift fences with pitfall and funnel traps can be a source of artificial aggregation of individuals and thus may attract potential predators. Spiders have been recorded preying on lizards of the genus *Enyalius* inside traps (Gomides et al. 2010. Herpetol. Rev. 41:221–222).

Rhinella pombali is distributed throughout the Atlantic Rainforest and its transitional areas with the cerrado, in the State of Minas Gerais and part of State of Rio de Janeiro (Baldissera et al. 2004. Arq. Mus. Nac. Rio J. 62[3]:255–282; Silveira et al. 2009. Biotemas 22[4]:231–235).

In this note we report the predation of *R. pombali* by army ants, *Labidus* sp. (Ecitoninae), within a funnel trap installed in the Reserva Biológica Municipal Santa Cândida (21.754917°S, 43.396833°W, WGS 84; 783 m elev.), an Atlantic Rainforest patch, in the municipality of Juiz de Fora, State of Minas Gerais, southeastern Brazil. The predation was observed by SCG and CHVR on 21 Jan 2009, at about 1600 h, who saw the column of ants (about 10 m long and 3 m wide) walk across the leaf litter and on vegetation along the drift fence. In one of the funnel traps a *R. pombali* was eaten by ants. When first observed, the individual was already dead, and consumption was complete in less than one hour. In Lajinha Municipal Park in the municipality of Juiz de Fora (21.792417°S, 43.380889°W; WGS84, 893 m elev.) on 28 Jan 2009, there was also a colony of *Labidus* observed to walk along the drift fences, but these ants encountered no amphibians or reptiles.

We thank W. L. Ouverney Jr. for field assistance and T. M. Machado for suggestions on the manuscript. We thank Cordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES) for financial support and IBAMA for the authorization for animal capture issued under the number 17074-1.

***SCAPHIOPUS HOLBROOKII* (Eastern Spadefoot). LOCOMOTION.** Alternate-leg swimming patterns are considered to be a unique behavioral characteristic of the primitive frog families Leiopelmatidae and Ascaphidae, with more advanced families of frogs using a synchronous-leg swimming pattern (Abourachid and Green 1999. J. Herpetol. 33:663–674). All of the more advanced anuran species reported by Abourachid and Green (1999, *op. cit.*) exhibited the typical, and more efficient, synchronous-leg swimming. In this familiar form of aquatic locomotion, both hind legs simultaneously move through a rapid extension propulsion stroke, which is then followed by a synchronized recovery stroke where both hind legs are simultaneously pulled back up to the body. Similar to the more advanced anurans (suborder Neobatrachia) used in the study, the primitive species *Bombina variegata* (suborder Archeobatrachia, family Bombinatoridae) also exhibits a synchronized swim kick pattern.

Here we report that *Scaphophus holbrookii* swims with the alternate-leg kick pattern exhibited by the most morphologically archaic extant species of frogs (Green and Cannetella 1994. Ethol. Ecol. Evol. 5:233–245). Field observations of *S. holbrookii* swimming in vernal pools in Cape May Co., New Jersey, USA, on the evening of 20 March 2010 (by DMG) and in Charles City Co., Virginia, USA, on the evening of 29 March 2010 (by JDK) confirm that this species swims with the same alternate-leg swimming pattern described by Abourachid and Green (1999, *op. cit.*). *Scaphiopus holbrookii* alternates the movements of its hind limbs and extends its forelimbs out in front of its body when swimming. Because *S. holbrookii* is in the suborder Mesobatrachia, this observation raises questions about the evolutionary point at which a synchronized pattern of aquatic locomotion became prominent in anurans.

TESTUDINES — TURTLES

***CHELONIA MYDAS AGASSIZII* (East Pacific Green Seaturtle). DIET.** The East Pacific Green Turtle is considered the most carnivorous of all Green Turtle subpopulations worldwide (Bjorndal 1997. *In* Lutz and Musick [eds.], The Biology of Sea Turtles, pp. 199–231. CRC press, Boca Raton, Florida). Novel green turtle diet items have been reported, including consumption of the sea pen, *Ptilosarcus undulatus* (Seminoff et al. 2002. Copeia 2002:266–268), pelagic red crabs, *Pleuroncodes planipes* (Lopez-Mendilaharsu et al. 2005. Aquatic Conserv: Mar. Freshwater Ecosyst. 15:259–269), tunicates and crustaceans (Amorocho and Reina 2007. Endang. Species Res. 3:43–51), hydrozoans, scyphozoans, nematodes, annelids, molluscs (Carrion-Cortez et al. 2010. J. Mar. Biol. Assoc. U.K. 1–9), and sponges, *Craniella* sp. and *Suberites aurantica* (Rodriguez-Baron 2010. MS thesis. Centro Interdisciplinario de Ciencias Marinas [CICIMAR-IPN]. 98 pp.). It has been suggested that such dietary diversity is a response to the energy requirements of these animals in the early life stages, facilitating nutritional (e.g., protein) gains for development and maturation (Bjorndal 1985. Copeia 1985:736–751) and optimizing digestion time (Amorocho and Reina 2008. J. Exp. Mar. Biol. Ecol. 360:117–124). It has also been noted that *C. mydas* diet is influenced by resource availability (Balazs 1980. NOAA Tech. Memo. NOAA-TM-NMFS-SWFS-7; Garnett et al. 1985. Wildl. Res. 12:103–112) and that diet selection is linked to the composition and capacity of the hind-gut microflora, which may change as turtles grow and/or occupy different habitats (Bjorndal 1980. Mar. Biol. 56:147–154).

During two field trips in 2009 we collected food samples from the esophagi of 21 Green Turtles (body mass 14–65 kg, and straight carapace length [SCL ± 0.1 cm] from 40.3–73.4 cm; mean SCL = 54.83 ± 83.6 cm) captured at Laguna Ojo de Liebre (LOL; 27.5908333–27.9166667°N and 113.9983333–114.1666667°W) located in the El Vizcaino Biosphere Reserve, Baja California Sur, Mexico. The anemone *Palythoa ignota* was present in 18 of the total samples, and it comprised 68.76% of the total volume. Turtle mean body condition index (BCI) was 1.48 (range = 1.25–2.06), similar to the values reported in previous studies (Seminoff et al. 2003. J. Mar. Biol. Assoc. U.K. 83:1355–1362; Koch et al. 2007. Mar. Biol. 153[1]:35–46) and indicative of good health of the animals (Bjorndal et al. 2000. Ecol. Appl. 10:269–282).

To our knowledge this is the first report of targeted anenome consumption by Green Turtles. The fact that *P. ignota* occurred in such high proportion among a substantial number (85.7%) of turtles suggests that this colonial cnidarian is a major food resource for Green Turtles at LOL, and that these turtles have the capacity to assimilate nutrients from this invertebrate species (Bjorndal 1990. Bull. Mar. Sci. 47[2]:567–570).

We thank the Grupo Tortuguero de las Californias A.C. for their assistance in the field work.

***CHELONIA MYDAS AGASSIZII* (Black [Pacific] Seaturtle). EPIBIONT BARNACLES.** The taxonomy of *Chelonia mydas* is controversial; some authors reject the designation of subspecies (e.g., Ernst and Lovich 2009. Turtles of the United States and Canada, 2nd ed., Johns Hopkins Univ. Press) but traditionally *Chelonia m. agassizii* Bocourt 1868 is the form recognized in the Pacific and Indian Oceans. A melanistic (black) form, *C. mydas carrinegra*, was described from the coast of Baja California (Caldwell 1962. Los Angeles Co. Mus. Contrib. Sci. 50:1–8) but black turtles are now known from other regions of the Pacific, including Japanese waters (Abe and Minami 2008. Nippon Suisan Gakkaishi 74:230–233). Three species of sea turtles are known to nest on the Japanese coast: *Caretta caretta*, *Chelonia mydas* (non-melanistic), and *Eretmochelys imbricata*, and the commensal barnacles of those sea turtles were listed by Hayashi (2009. Umigame Newsletter of Japan 81:2–17). There are apparently no previous records of the barnacles attached to black *C. mydas* from Japan. Additionally, few records exist for epibionts on Black Seaturtles anywhere (Green 1998. NOAA Tech. Mem. NMFS-SEFSC-412. p. 63; Lazo-Wasem et al. 2007. Bull. Peabody Mus. Nat. Hist. 48:153–156; Nichols 2003. Biology and Conservation of Sea Turtles in

FIG. 1. The barnacle *Platylepas hexastylos* on carapace and plastron of *Chelonia mydas agassizii*.

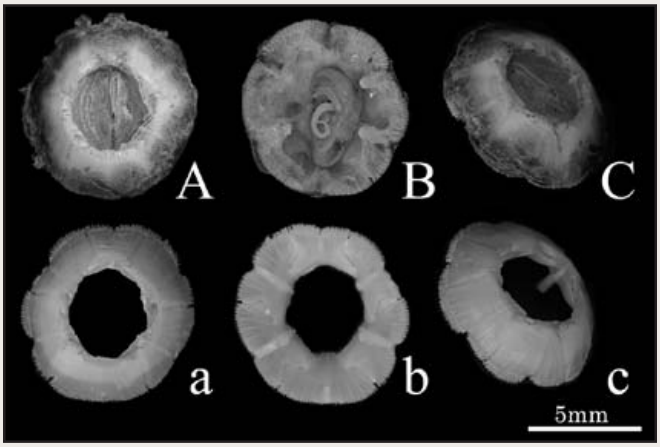

FIG. 2. Close-up of the barnacles *Platylepas hexastylos* found on *Chelonia mydas agassizii*.

Baja California, Mexico. PhD dissertation, University of Arizona, Tucson. 474 pp.; Zullo 1991. *In* M. J. James [eds.], Galápagos Marine Invertebrates: Taxonomy, Biogeography, and Evolution in Darwin's Islands, pp. 173–192. Plenum Press, New York). In this note, we report the epibiont barnacles found on a Black Seaturtle from Japanese waters. This report also represents the northernmost record of a Black Seaturtle and the first record of barnacles attached on a Black Seaturtle in the western Pacific.

On 7 September 2009, a black *C. mydas* was caught in a fishing net at Miyako, Iwate, Japan (39.40°N, 141.58°E). This turtle was measured (standard carapace length, 53.8 cm; standard carapace width, 43.8 cm) and tagged (Sea Turtle Association of Japan [STAJ] plastic tags, No. 64800 on the right hind flipper and No. 64801 on the left hind flipper), and a sample of barnacles were collected and preserved in 99% ethanol solution, and identified in the laboratory. Materials examined were deposited in Fujukan, the Museum of the University of Ryukyus, under accession numbers RUMF-ZC 02009–02011. After investigation, the animal was released but unfortunately it was stranded the next day (fishermen in Kyofuku-Maru, Fisheries Cooperative Association of Funakoshi Bay, pers. comm.). This turtle had many barnacles (>100 individuals) attached on the carapace, plastron, and flippers. All of these barnacles were identified as *Platylepas hexastylos* (Fabricious, 1798) (Fig. 1). Previous studies reported the occurrences of *Platylepas decorata* Darwin 1854, *Stomatolepas praegustator* Pilsbry 1910, *Cylindrolepas darwiniana* Pilsbry 1916, and *Platylepas hexastylos* on Black Seaturtles in the eastern Pacific. *Platylepas hexastylos* is cosmopolitan and known to attach to various species of sea turtles; phylogeography and population genetics of this species might provide information on the macro scale distribution and migration of sea turtles.

The field study was assisted by STAJ, and supported by grants from National Geographic, the Japan Society for the Promotion of Science (19255001), and JSPS Research Fellowship for Young Scientists (21-7432). We gratefully acknowledge the Hidejima set net fishermen in the Fisheries Cooperative Association of Miyako for providing the living Black Seaturtle specimen.

***CHELYDRA SERPENTINA* (Common Snapping Turtle). BIFID TAIL.** Regeneration can be defined as the ability to reproduce relatively complicated organs or structures after they have been lost through injury (Kuchling 2005. Chelon. Cons. Biol. 4[4]:935–937). The best examples of tail regeneration are found in extant reptiles that exhibit caudal autotomy, for example, lizards (with the exception of most agamids, a few iguanids, and the varanids) and tuataras (*Sphenodon*). Turtles do not exhibit caudal autotomy and very little is known about their tail regeneration. Kuchling (2005, *op. cit.*) reports the occurrence of bifid tail regeneration in an individual adult male *Emydura* sp. in Western Australia, which indicates that the tails of chelonians may have some regenerative capacity. Herein, I report a bifid tail, and possible tail regeneration, in an individual *Chelydra serpentina* found in a pond in New York City. This is apparently the first published report of a bifid-tailed turtle in North America.

I captured an adult male *Chelydra serpentina* (straight-line carapace length = 414 mm, plastron length = 330 mm, carapace width = 376 mm) with a bifid tail in a baited hoop trap in a 0.4-ha pond in Alley Pond Environmental Center, Queens, New York, USA, on 25 September 2007. The tail of the turtle was much shorter than is typical. The tip of the tail was bifurcated in the horizontal plane with mirror duplication and the bifurcation point was positioned 55 mm posterior from the cloaca. The same individual was recaptured several times in 2008 and 2009 as a part of a long term mark-recapture study.

Turtles have demonstrated the capacity to regenerate their shells but the regenerative capability of the turtle tail is poorly known. Etheridge (1967. Copeia 1967:699–721) suggested that in non-autotomous lizards, extensive tail regeneration only occurs after tail loss involving damage to vertebrae (*in* Kuchling 2005, *op. cit.*). Previous research suggests that the bifid or multiple regeneration of a tail most likely results from damage to a vertebra. Records of bifid tail regeneration have been published for several lizards (*in* Mata-Silva 2010. Herpetol. Rev. 41:352–353). However, not all cases of multiple tail occurrences can attributed to regeneration; cases of developmental axial bifurcation have also been reported (Kuchling 2005, *op. cit.*). Kuchling (2005, *op. cit.*) demonstrated that the bifid tail of the *Emydura* sp. was a case of regeneration, based on a radiograph. Because there was no radiographic or histological examination on the bifid-tailed *Chelydra serpentina* reported here, it cannot be determined whether this specimen was an example of a regeneration phenomenon or represents a case of axial bifurcation. Further investigations are needed to better understand tail regeneration in turtles.

I acknowledge the staff of Alley Pond Environmental Center and Peter Warny, who provided valuable support and logistics in the field. I thank Anders Rhodin who kindly provided literature sources and Gerard Kuchling for providing valuable comments on the manuscript.

SHAHRIAR CAESAR RAHMAN, Department of Biology, Brooklyn College, Brooklyn, New York 11210, USA; e-mail: Caesar_rahman2004@yahoo.com.

***CHELYDRA SERPENTINA* (Snapping Turtle). OVERWINTER TISSUE NECROSIS.** On 15 April 2007, an unusually warm spring day (24°C), several large Snapping Turtles were surface basking in shallow water in the northwest corner of Gimlet Lake, Crescent Lake National Wildlife Refuge, Garden County, Nebraska, USA. The site was a flooded pool ca. 10 m × 20 m, fed by small artesian springs along the shore, and was the probable overwintering site for these turtles. I was able to hand-capture one individual, a male of 36 cm carapace length. Subsequent cold weather and dispersal of the snappers from the pool prevented capture of other individuals in the area. Closer inspection of the turtle revealed considerable tissue damage and necrosis only to the tongue, roof of the mouth, and the extremities (Figs. 1A–C), and was consistent with severe frostbite. This was my first observation of this condition among >2000 captures of snappers on the Refuge over thirty years. Following processing, this turtle was released at the capture site, and has not been recaptured, but it is not known whether the turtle survived this condition. It is also not clear how this damage was incurred, but it was consistent with terrestrial activity during sub-freezing activity. Winter temperatures had been erratic (December, 3.2°C above normal; January, 0.9°C below; February, 1.6°C below; March, 5.2°C above; and April, 0.3°C below), and perhaps this turtle had been active during March (the warmest March in at least 40 years), and

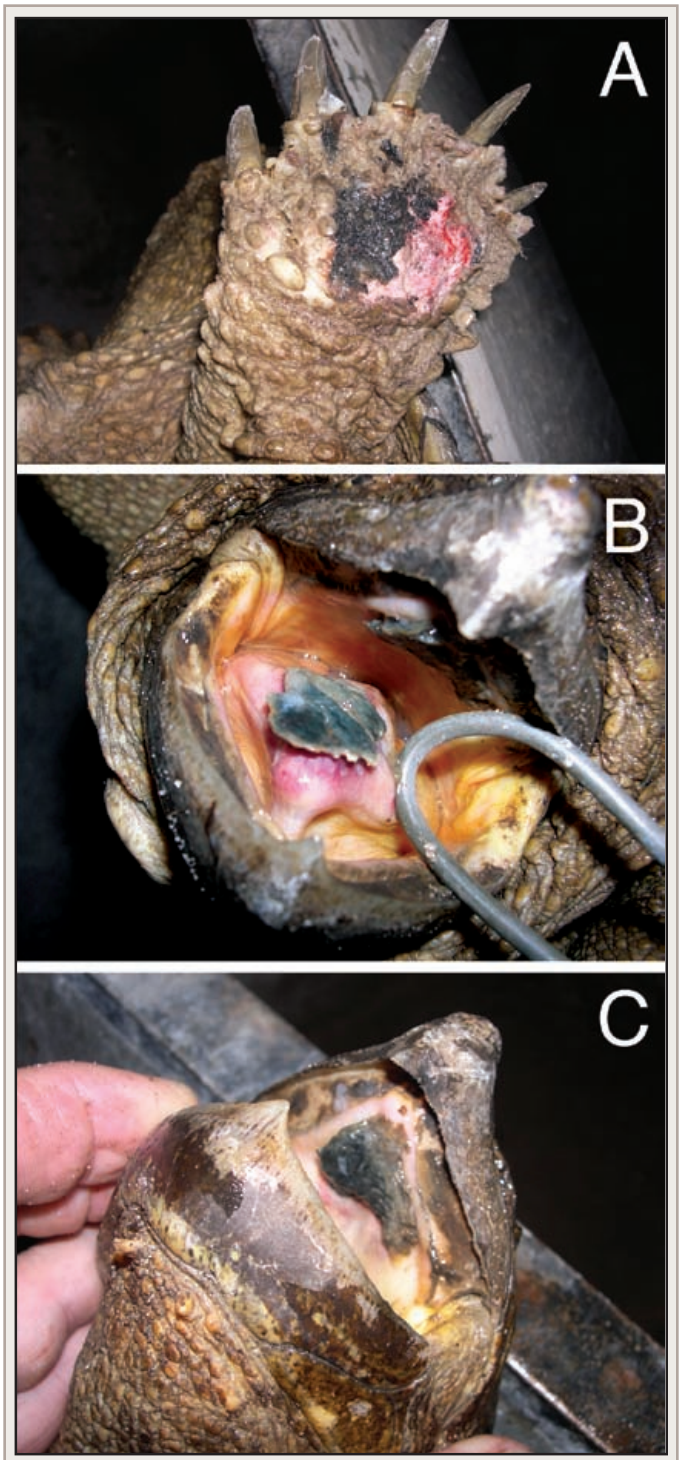

FIG. 1. Severe necrosis of ventral surface of right rear foot (A, top), dorsal surface of tongue (B, middle), and ventral surface of the palate (C, bottom) on a Nebraska Snapping Turtle captured 15 April 2007.

subsequent cold weather forced its terrestrial (or over-ice) migration to warmer water.

JOHN B. IVERSON, Department of Biology, Earlham College, Richmond, Indiana 47374, USA; e-mail: johni@earlham.edu.

***GOPHERUS AGASSIZII* (Desert Tortoise). NON-NATIVE SEED DISPERSAL.** Sahara Mustard (*Brassica tournefortii*) is a non-native, highly invasive weed species of southwestern U.S. deserts. Sahara Mustard is a hardy species, which flourishes under many conditions including drought and in both disturbed and undisturbed habitats (West and Nabhan 2002. *In* B. Tellman [ed.], Invasive Plants: Their Occurrence and Possible Impact on the Central Gulf Coast of Sonora and the Midriff Islands in the Sea of Cortes, pp. 91–111. University of Arizona Press, Tucson). Because of this species' ability to thrive in these habitats, *B. tournefortii* has been able to propagate throughout the southwestern United States establishing itself in the Mojave and Sonoran Deserts in Arizona, California, Nevada, and Utah. Unfortunately, naturally disturbed areas created by native species, such as the Desert Tortoise (*Gopherus agassizii*), within these deserts could have facilitated the propagation of *B. tournefortii*. (Lovich 1998. *In* R. G. Westbrooks [ed.], Invasive Plants, Changing the Landscape of America: Fact Book, p. 77. Federal Interagency Committee for the Management of Noxious and Exotic Weeds [FICMNEW], Washington, DC). However, Desert Tortoises have never been directly observed dispersing Sahara Mustard seeds. Here we present observations of two Desert Tortoises dispersing Sahara Mustard seeds at the interface between the Mojave and Sonoran deserts in California.

On 24 May 2010, we observed several Sahara Mustard seeds on the carapace of two male Desert Tortoises at our study site, a utility-scaled renewable energy wind park (33.95168°N, 116.667295°W, WGS84) in southern Riverside County, California. One tortoise had six *B. tournefortii* seeds adhered to the cervical scute and first vertebral scute, the seam between the first right marginal and the cervical scute, and on the dried epoxy holding the radio antenna to the carapace (Fig. 1). Another tortoise had a single Sahara Mustard seed on the second vertebral scute. Interestingly, Sahara Mustard has several modes of seed dispersal including, when moist, adhering to mobile organisms by a sticky substance (Minnich and Sanders 2000. *In* Bossard et al. [eds.], Invasive Plants of California's Wildlands, pp. 68–72. University of California Press, Berkeley, California), which explains our observations. Sahara Mustard seed's primary dispersal mechanism

FIG. 1. A male *Gopherus agassizii* with five visible red seeds of *Brassica tournefortii* adhered to its carapace.

includes wind (i.e., tumbleweed action) and rodents that collect, cache, and consume them (Bangle et al. 2008. West. N. Amer. Nat. 68:334–342). Although the observations reported here provide evidence that Desert Tortoises can also disperse seeds of Sahara Mustard, this mechanism, unlike wind and similar to rodent dispersal, has the potential for specifically introducing the non-native species in disturbed habitats, such as burrow aprons. Others have also reported the potential for Desert Tortoises to disperse other non-native species, such as Red Brome (*Bromus madritensis rubens*; Medica and Eckert 2007. Herpetol. Rev. 38:446–448).

LOVICH** (e-mail: jeffrey_lovich@usgs.gov), U.S. Geological Survey, Southwest Biological Science Center, c/o Northern Arizona University, Applied Research & Development Bldg., Suite 150, P.O. Box 5614, Flagstaff, Arizona 86011, USA.

***MAUREMYS RIVULATA* (Balkan Terrapin). ANOPHTHALMIA.** Congenital defects of the eye, such as anophthalmia, microophthalmia, and cyclopia have been reported in many species of mammals (e.g., Fantes et al. 2003. Nat. Gen. 33:462–462), birds (Berger and Howard 1968. Condor 70:386–387), reptiles (Frye 1991. Biomedical and Surgical Aspects of Captive Reptile Husbandry, Volume II. Krieger Publ. Co., Malabar, Florida; Hindebrand 1930. J. Elisha Mitchell Sci. Soc. 46:41–53; Millichamp 1990. Proc. Amer. Assoc. Zoo Vet., American Association of Zoo Veterinarians, South Padre Island, Texas, pp. 297–301) and amphibians (e.g., Cheong et al. 2000. J. Comp. Pathol. 123:110–118; Millichamp 1990, *op. cit.*; Schoff et al. 2003. J. Wildl. Dis. 39:510–521), but reports of these conditions are uncommon, especially in the wild.

During a recent fieldtrip in the Southern Cyclades (Greece) in 2009, we examined 814 *Mauremys rivulata* specimens and found one (0.00123%) juvenile specimen near the barrage of Steno, in Livadi on Serifos Island, expressing this deficiency. This specimen clearly lacked eyes (Figs. 1, 2) and also possessed a reduced dental bone. We analyzed the skull dimensions with a portable RX-apparatus (AJEX 9020H, X-ray equipment Verachtert, Antwerp, Belgium). Comparison with a normal turtle (Figs. 1–2) of similar size clearly showed overall skull malformations of the examined specimen. The specimen with bilateral anophthalmia clearly has an enlarged os dentale, reduced maxilla and premaxilla. Additionally, the os nasale, os frontale, and the parietal bones do not appear to be ossified.

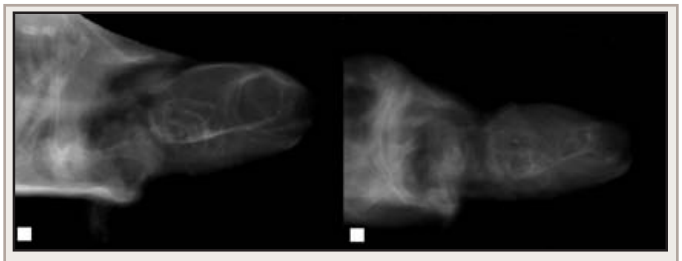

FIG. 1. Radiographic pictures of *Mauremys rivulata* with normal head (left) and with bilateral anophthalmia (right). The white square on the bottom left of each picture represents 1 mm.

FIG. 2. Photographic pictures of specimen with normal head (left) and with bilateral anophthalmia (right). The black and white bars on the scale represent 1 mm each, for a total bar length of 5 mm.

Bilateral anophthalmia is the most rare and severe form of structural eye malformation. Causes of this anomaly can both be induced by genetic mutations (e.g., Fantes et al. 2003, *op. cit.*) or by physical conditions during development (e.g., pathological shortening of the embryonic axis; Ewert 1985. Biology of the Reptilia, Vol. 14, Development A, pp. 75–267. Wiley, New York), but is usually undetermined (e.g., Millichamp 1990, *op. cit.*). All research was conducted under permits provided by the Greek Herpetological Society and the Greek Ministry of Agriculture. All procedures followed were approved by the University of Antwerp Animal Care and Use Committee. Jonathan Brecko is funded by a PhD. grant of the Instituut voor de Aanmoediging van Innovatie door Wetenschap en Technologie in Vlaanderen (Institute for the Promotion of Innovation by Science and Technology in Flanders).

BART VERVUST (e-mail: bart.vervust@ua.ac.be) and **JONATHAN BRECKO** (e-mail: jonathan.brecko@ua.ac.be), Laboratory for Functional Morphology, University of Antwerp, Universiteitsplein 1, B-2610 Antwerp, Belgium.

***PELODISCUS SINENSIS* (Chinese Softshell Turtle). EXTRALIMITAL WINTER SURVIVAL.** *Pelodiscus sinesis* is a medium-sized softshell turtle that ranges from from extreme southeastern Siberia (between the Ussuri and the Amur River drainages) and adjacent Korea through central and southern China, Vietnam, and the islands of Hainan and Taiwan. It has been introduced into the Hawaiian Islands, Guam, one of the Mariana Islands, one of the Bonin Islands, Timor, and California (Lever 2003. Naturalized Amphibians and Reptiles of the World. Oxford University Press, New York; Ernst and Barbour 1989. Turtles of the World. Smithsonian Press, D.C.). *Pelodiscus sinensis* is the most common turtle species bred in turtle farms in Asia (Haitao et al. 2008. Oryx 42[1]:147–150. They are exported to United States and are often sold in Asian food markets of New York City. Here, we report winter survivorship of an individual *Pelodiscus sinensis* in New York City.

We captured an adult male *Pelodiscus sinensis* at Windmill Pond, Alley Pond Environmental Center, Queens, New York (40.4542°N, 73.4516°W) (Fig. 1). Photographs were verified by Balazs Farkas, Hungarian Natural History Museum, Budapest, Hungary. Windmill pond is approximately 0.4 ha, 1.5 m deep, muddy-bottomed, and has abundant aquatic vegetation. Non-native *Trachemys scripta elegans* are the most common turtles in this pond, followed in abundance by native *Chelydra serpentina* and *Chrysemys picta*. Turtle trapping was conducted in this pond starting in 2007 for a long term study. The *P. sinensis* was captured on 24 July 2009 (carapace length = 238 mm; plastron length = 172 mm; weight = 1620 g) and recaptured on 27 July 2010, essentially unchanged. The turtle was captured in a baited hoop net on both occasions. The recapture site was less than 10 m from the original capture site. The turtle was photographed on each capture and we confirmed it as the same individual based

on scar marks on carapace, injury mark on lower jaw, and unique pattern of dark blotches on plastron. The turtle was missing part of its lower jaw, in both 2009 and 2010, but otherwise appeared healthy and in good condition. The turtle had plastral blotches, which suggest that it is probably originated from central Vietnam or a turtle farm anywhere in Vietnam or China (B. Farkas, pers. comm.,13 August 2010) The northernmost population of *P. sinensis* in northern China and Russian Far East hibernate over winter, where the summer temperatures in the hottest month barely exceed 20°C. There are reports of *P. sinesis* in Central and Prospect Parks in New York City but this is the first known report of overwinter survivorship in New York, indicating that they are capable of surviving the local climatic conditions of that area.

FIG. 1. Lateral (top) and ventral (bottom) view of *Pelodiscus sinensis* found in Windmill Pond, Queens, New York.

SHAHRIAR C. RAHMAN, Department of Biology, Brooklyn College, Brooklyn, New York 11210, USA (e-mail: Caesar_rahman2004@yahoo.com); **PETER R. WARNY**, Port Washington, New York 11050 USA (e-mail: prwarny@yahoo.com).

***STERNOTHERUS MINOR MINOR* (Loggerhead Musk Turtle). DIET.** The diet of *Sternotherus minor minor* has been well-documented in the literature and includes crayfish, snails, plant material, insects, millipedes, clams, fish, aquatic invertebrates, carrion, small vertebrates, algae and other aquatic plants, small turtles, and *Goniobasis* snails (Ernst and Lovich 2009. Turtles of the United States and Canada, 2nd ed. Johns Hopkins University Press, Baltimore, Maryland). *Sternotherus minor peltifer* has been reported to consume insects, snails, filamentous algae, vascular plants, riverweed (*Podostemum*), clams, crayfish, spiders, fish, bits of rock, and detritus (Ernst and Lovich 2009, *op. cit.*). Herein I report evidence of *S. m. minor* consuming fruits of the Sugarberry Tree, *Celtis* cf. *laevigata*.

On 2 January 2006 an adult male *S. m. minor* (11–12 cm carapace length) was captured along the Itchetucknee River in north-central Florida. The turtle was placed in a 5-gallon bucket of shallow water until it could be photographed. Shortly after capture, the turtle defecated in the bucket. The fecal sample consisted almost exclusively of the crushed remains of endocarps of *C.* cf. *laevigata*. Only crushed (no whole) fruits were found in this sample.

Subsequent investigation of preserved (pre-dissected only) *Sternotherus m. minor* housed in the FLMNH Division of Herpetology collection also yielded small amounts of *Celtis* endocarps within their digestive tracts. Most endocarps found had been crushed (e.g., UF 71608 and UF 71604), but a whole seed was also found in the intestine of one turtle (UF 71604).

As a result of these findings, ca. 14 *C. leavigata* fruits were added to the enclosure of two captive *S. m. minor*. Both floating and sunken fruits were readily consumed by the captive turtles within minutes of deposition. The fruits were manipulated in the turtles' jaws until the hard endocarps were broken, indicated by a loud popping sound, after which the turtles would swallow. Any fragments of exocarps and/or endocarps inadvertently expelled during intake were pursued and eaten.

Questions arise as to what frequency *Celtis* fruits are consumed by *Sternotherus m. minor*, what role *Celtis* seeds might play with regards to nutritional value, morphology, and habitat preferences of *S. m. minor*, as well as the role of *S. m. minor* acting as a potential seed disperser through the riparian systems it occupies. The expanded alveolar surfaces in *S. m. minor* are a presumed adaptation for durophagy—a diet comprised primarily of mollusks such as snails and clams (Ernst and Lovich 2009, *op. cit.*). This adaptation also allows *S. m. minor* to completely crush the rigid seeds of *Celtis*. Crushed *Celtis* endocarps do resemble crushed gastropod shells, and for this reason it is plausible that *Celtis* remains might have been overlooked or misidentified by investigators in previous dietary studies of *S. minor*, particularly if mixed with crushed gastropod shells. Because *Celtis*

sp. endocarps contain high concentrations of calcium carbonate (Yanovsky et al. 1932. Science 75[1952]:565–566), future studies could explore the nutritional of these fruits in *S. minor*. Additionally, the range and associated riparian habitats of *C. laevigata* are strikingly similar to those of which were once referred to as the *Sternotherus carinatus* complex, which is currently recognized as *Sternotherus carinatus*, *Sternotherus depressus*, *S. m. peltifer*, and *S. m. minor*. Further work might explore the extent of any dependency or even interdependency between this group and *C. laevigata*.

I thank Donna Ruhl for help in identifying *Celtis* remains, K. Krysko for allowing me to examine preserved specimens in the FLMNH Division of Herpetology collection. K. Krysko, D. Ehret, A. Hastings, M. Nickerson, and J. Harding provided helpful comments on this manuscript.

CROCODYLIA — CROCODILIANS

***ALLIGATOR MISSISSIPPIENSIS* (American Alligator). DIET.** *Alligator mississippiensis* inhabits swamps, marshes, and other freshwater bodies of water in the southeastern United States (Ambercrombie and Delaney 1986. J. Wildl. Manag. 50:348–353). It is an apex predator, an opportunistic eater, and it is considered a keystone species (Abercrombie and Delaney 1986, *op. cit.*). *Alligator mississippiensis* is known to prey upon crustaceans, such as Blue Crab (*Callinectes sapidus*), fish, snakes, turtles, birds, and mammals, such as Nutria (Valentine 1972. J. Wildl. Manag. 36:809–815). Cannibalism has also been observed in this species (Giles and Childs 1949. J. Wild. Manag. 13:16–28).

We collected and dissected 20 stomachs of *A. mississippiensis* to investigate stomach parasitism. Specimens had been captured and killed by hunters during the alligator harvesting and hunting season up to 24 h prior at a processing center from 26–29 August 2010. Alligators were caught in the East Zone, a geographic zone designated by the Louisiana Fisheries and Wildlife Department. Dissection of one of the stomachs yielded an intact specimen that was later identified as a Gulf Crayfish Snake (*Regina rigida sinicola*). Research has shown that crocodilians can digest prey items within 12 h if the prey is not large and does not contain bony plates or an exoskeleton (Diefenbach 1975. Comp. Biochem. Physiol. 51:259–265). Therefore, it may be inferred that the snake was ingested shortly before the capture of the alligator.

The snake was identified based upon scalation, morphology, and coloration (Fig. 1). This is the first report of *R. r. sinicola* as a prey item of *A. mississippiensis*, although the congeneric *Regina alleni* has been previously documented (Delany and Abercrombie 1986, *op. cit.*).

We thank Chris Plott and the American Tanning and Leather Company for allowing us to conduct our research, and their help in obtaining samples. We also thank Ruth Elsey and the Louisiana Department of Wildlife and Fisheries for all their assistance in this project.

Young Dr. S., Los Angeles, California 90095, USA.

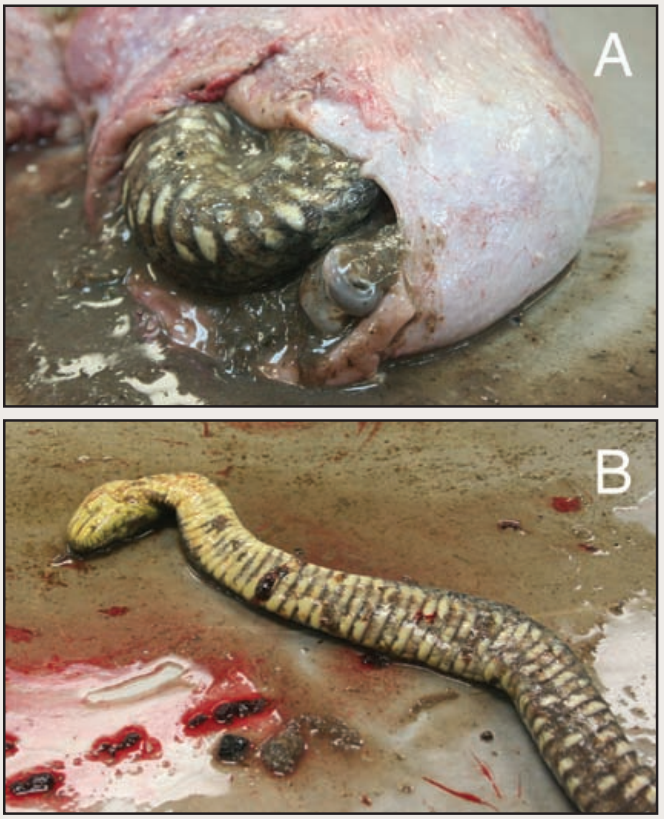

FIG. 1A. *Regina rigida sinicola* in the stomach of *Alligator mississippiensis*. 1B. Underside of *Regina rigida sinicola* after removal from stomach.

***CAIMAN CROCODILUS* (Spectacled Caiman). PREY.** Crocodilians are top predators adapted to aquatic habitats (Shyrley et al. 2009. Oryx 43:136–145). The diet of *Caiman crocodilus* has been reported to consist of terrestrial invertebrates, such as freshwater crabs and coleopterans, more so than terrestrial vertebrates, such as mammals, reptiles, and anurans (Magnusson et al. 1987. J. Herpetol. 21:85–95; Thorbjarnarson. 1993. Herpetologica 49:108–117).

We conducted spotlight surveys from a boat to evaluate crocodilian populations at Sapucuá Lake (between 1.75°N, 56.31°W and 1.86°N, 55.98°W) in the municipality of Oriximiná, in the northern part of the state of Pará, Brazil. On 26 May 2010 at 1900 h, one *Caiman crocodilus* (estimated SVL 39.5 cm) was observed with a Marine Toad (*Rhinella marina*; SVL = 95 mm; mass = 80 g) in its mouth biting down on the toad's parotoid glands. The caiman escaped before it could be captured for data collection, leaving the dead toad behind. The amphibian was collected and deposited at the herpetological collection of Museu de História Natural Capão da Imbuia at Curitiba, Paraná state, Brazil (MHNCI 7186).

Parotoid glands contribute to anuran protection against predators and parasites (Almeida et al. 2007. Contrib. Zool. 76:145–152; Sakate and Lucas de Oliveira. 2000. J. Venom. Anim. Toxins 6:46–58), due to pharmacological activity. Indolealkylamine is the main compound found in the skins of bufonids (Cei et al. 1972. *In* W. F. Blair [ed.], Evolution in the Genus *Bufo*, pp. 233–243. University of Texas Press, Austin, Texas), acting as a vasoconstrictor, convulsant, hallucinogen, and cholinergic agent

(Maciel et al. 2003. Comp. Biochem. Physiol. B 134:641–649). In Australia, where *R. marina* was introduced, *Crocodylus johnstoni* individuals of intermediate size class died after the ingestion of the toads due to the absence of physiological adaptations against its highly toxic secretions (Letnic et al. 2008. Biol. Conserv. 141:1773–1782). However, *Crocodylus porosus*, which naturally coexist with *R. marina*, presented a better performance against the bufotoxin when compared to *C. johnstoni* during physiological tests (Smith and Phillips 2008. Pac. Conserv. Biol. 12:40–49). Predation behavior on *Rhinella marina* by Schneider's Dwarf Caiman (*Paleosuchus trigonatus*) was described in the state of Pará, Brazil (Assis and Santos 2007. Herpetol. Rev. 38:45); however, there are no data available regarding the interaction between *R. marina* and *C. crocodilus*. Among terrestrial vertebrates reported in the diet of *C. crocodilus*, anurans are few (Magnusson et al. 1987. J. Herpetol. 21:85–95; Thorbjarnarson 1993, *op. cit.*; Da Silveira and Magnusson 1999. J. Herpetol. 33:181–192). Percentage of prey occurrence analysis and relative digestibility can bias the presence of vertebrate prey items in the diet of *C. crocodilus* (Thorbjarnarson 1993, *op. cit.*). We believe that field observations on crocodilian foraging behavior can provide relevant data about predator-prey interactions. Meanwhile, captive experiments can help in understanding feeding habits and preferences as well as in investigating resistance to bufotoxins.

We thank MRN (Mineração Rio do Norte S.A.) for the financial support of the studies conducted on the herpetofauna of FLONA Saracá-Taquera, Pará State, and Instituto Chico Mendes de Conservação da Biodiversidade, Porto Trombetas (ICMBio), PA unit, for permits.

VICTOR BOTELHO GRAÇA VÉRAS BATISTA, Laboratório de Geoprocessamento, Universidade Católica de Brasília, EPCT QS 7, Taguatinga, Distrito Federal, Brazil (e-mail: victorbgvb@gmail.com); **SÉRGIO AUGUSTO ABRAHÃO MORATO**, STCP Engenharia de Projetos Ltda. R. Euzébio da Motta, 450, CEP 80.530-260, Curitiba, Paraná, Brazil, and Universidade Tuiuti do Paraná, R. Sidney Rangel Santos, Curitiba, Paraná, Brazil; **ANDERSON PAZ**, Quadra 3, conjunto G, casa 23, Sobradinho, Distrito Federal, Brazil, CEP 73030-037.

***CROCODYLUS MORELETII* (Morelet's Crocodile). SMALL POND USE.** At 0047 h on 14 June 2008, during rainy conditions, we encountered a juvenile (571 mm SVL) female *Crocodylus moreletii* in a small pond (3.0 m × 4.3 m, 70 mm deep) in the middle of a small road surrounded by a brackish water wetland in Reserva de la Biosfera Los Petenes, Campeche, México (20.087032°N, 90.401258°W). At 0139 h, we observed another juvenile female *C. moreletii* (700 mm SVL) in a second small pond (1.4 × 3.0 m, 90 mm deep at 20.089948°N, 90.433983°W).

These observations are of interest since both ponds were in the middle of a small road surrounded by brackish water wetlands that are more indicative habitat for this species. We encountered another three *C. moreletti* (one adult, two juveniles) in open waters within the actual wetlands the same night. No previous reports exist of this behavior (Alvarez del Toro and Sigler 2001. Los Crocodylia de México. IMERNAR, PROFEPA, México 134 pp.). It is possible that the animals utilizing these smaller sites may take advantage of the low salinity in the rainwater filled ponds or the small ponds may provide food resources based on the potential prey we observed in similar ponds on this area (*Lithobates brownorum, Leptodactylus melanonotus, Ollotis valliceps, Smilisca baudinii*).

SQUAMATA — LIZARDS

***AMEIVA CORAX* (Little Scrub Island Ground Lizard). FEEDING BEHAVIOR.** *Ameiva corax* is endemic to Little Scrub Island, off the northeast coast of Anguilla in the British West Indies (18.308°N, 62.967°W). It is reported to consume the eggs of seabirds that nest on the island (Hodge et al. 2003. The Reptiles and Amphibians of Anguilla, British West Indies. Anguilla National Trust, Anguilla. 72 pp.). Herein we report on an individual lizard of this species opening, partially consuming, and ultimately killing the chick of a Laughing Gull (*Larus atricilla*) nesting on the island (Fig. 1).

At 0904 h on 12 June 2009 we noticed a lizard in a gull nest attempting to open one of three eggs present. The egg was opened in less than one minute; it is unclear whether the lizard cracked the egg or whether it had already been cracked by an emerging chick. We have observed other lizards cracking and consuming the contents of gull eggs in earlier stages of development, but since it appeared to be near hatching, the chick may have cracked the egg itself. Nevertheless, the lizard successfully opened the egg and we monitored its activity from ca. 5 m away. Once the egg was opened, the lizard first consumed the yolk sac, then began to claw and bite at the lower abdomen of the chick, eventually opening a hole in the chick's skin, pulling out and consuming part of its intestinal tract. Although the lizard bit and clawed at other parts of the chick, particularly the legs and wings, it did not pierce the skin elsewhere. The lizard (individually identifiable by

FIG. 1. *Ameiva corax* consuming the intestinal tract of a Laughing Gull (*Larus atricilla*) chick.

its shedding skin pattern) left the nest and returned three times between 0910 and 0930 h. When the lizard left the nest at 0930 h, the chick was still alive and moving. An adult gull returned to the nest at 0930h and incubated the remaining eggs. We monitored the nest until 1000 h, at which point the chick was still alive and an adult gull was on the nest. The chick was dead at 1230 h when we next checked on it.

We thank the Government of Anguilla for allowing us to work on Little Scrub Island. We are particularly grateful to Karim Hodge and Rhon Conner in the Department of the Environment for their support, encouragement, and advice. We also thank Captain Nature Boy Webster for transporting us to and from the island every day.

MARIA EIFLER and **DOUGLAS EIFLER**, Erell Institute, 2808 Meadow Drive, Lawrence, Kansas 66047, USA; e-mail: meifler@erellinstitute.org.

***AMEIVA LEPTOPHRYS* (Delicate Ameiva). ENDOPARASITES.** *Ameiva leptophrys* frequents lowland humid forests of southwestern Costa Rica and Panama to western Colombia (Savage 2002. The Amphibians and Reptiles of Costa Rica. A Herpetofauna Between Two Continents, Between Two Seas. Univ. Chicago Press, Chicago, Illinois. 934 pp.). There are, to our knowledge, no reports of helminths from *A. leptophrys*. The purpose of this note is to establish the initial helminth list for *A. leptophrys* as part of an ongoing survey of lizard helminths from Central America.

Six *A. leptophrys* (mean SVL = 112.3 mm ± 17.4 SD, range: 85–130 mm) from Costa Rica were examined from the herpetology collection of the Natural History Museum of Los Angeles County (LACM), Los Angeles, California: Limón Province (LACM 174920); Puntarenas Province (LACM 174922–174924, 174927, 174928). Lizards were collected 1963–1967. The digestive tract was removed and the esophagus, stomach, small and large intestines were examined for helminths using a dissecting microscope. Nematodes and cystacanths were cleared in a drop of glycerol on a microscope slide, cover-slipped and studied using a compound microscope. Three species of Nematoda were found: *Physaloptera retusa* (stomach) prevalence, number infected/number examined × 100 = 83%, mean intensity, mean number helminths ± 1 SD = 49.8 ± 33.6 SD, range = 2–85; *Spinicauda spinicauda* (large intestine) prevalence = 67%, mean intensity = 3.8 ± 2.2 SD, range = 1–6 and two ascarid larvae (Angusticaecinae) (body cavity) prevalence = 17% and one species of Acanthocephala as 11 cystacanths (body cavity) prevalence = 17%. Helminths were deposited in the United States National Parasite Collection (USNPC), Beltsville, Maryland: *Physaloptera retusa* (USNPC 103860); *Spinicaud spinicauda* (USNPC 103861); Ascarid larvae (USNPC 103862); Oligacanthorhynchid cystacanths (USNPC 103863).

Physaloptera retusa is widely distributed in the Western Hemisphere. Records are summarized in McAllister et al. (2010. Comp. Parasitol. 77:184–201). Physalopterid nematodes utilize insect intermediate hosts (Anderson 2000. Nematode Parasites of Vertebrates. Their Development and Transmission. CABI Publishing, Oxon, UK, 650 pp.). Lizards are infected through their diet. *Spinicauda spinicauda* is known from a variety of South American lizards (Baker 1987. Mem. Univ. Newfoundland, Misc. Pap. 11:1–325; Ramallo et al. 2009. J. Parasitol. 95:1026–1028). Lizards become infected when they ingest eggs; no intermediate host is utilized (Anderson 2000, *op. cit.*). Eggs of various species assigned to the order Ascaridida, Angusticaecinae will hatch in a variety of vertebrate intermediate hosts and develop into third-stage infective larvae (Anderson 2000, *op. cit.*). Because these larvae were in cysts, the possibility that *A. leptophrys* was serving as a transport (= paratenic host) must be considered. Cystacanths are larval forms infective to the definitive host (Kennedy 2006. Ecology of the Acanthocephala. Cambridge Univ. Press, Cambridge, UK. 249 pp.) and reach the lizard when it ingests an infected insect. No further development occurs in the lizard which serves as a paratenic transport host. *Physaloptera retusa*, *Spinicauda spinicauda*, ascarid larvae and oligacanthorhynchid cystacanths in *A. leptophrys* are new host records. Costa Rica is a new locality record for *S. spinicauda*.

We thank Christine Thacker (LACM) for permission to examine individuals of *A. leptophrys*, which are part of the Costa Rica Expeditions Collection donated to LACM in 1998 by Jay M. Savage. Cecilia Nava and Daisy Salguero (Whittier College) assisted with dissections.

STEPHEN R. GOLDBERG, Whittier College, Department of Biology, Whittier, California 90608, USA (e-mail: sgoldberg@whittier.edu); **CHARLES R. BURSEY**, Pennsylvania State University, Shenango Campus, Department of Biology, Sharon, Pennsylvania 16146, USA (e-mail: cxb13@psu.edu).

***ANOLIS ALTAE* (High Anole). ENDOPARASITES.** *Anolis altae* occurs in premontane and lower montane zones of the Cordillera de Tilarán, Cordillera Central and Cordillera de Talamanca of Costa Rica at elevations of 1220 to 2000 m (Savage 2002. The Amphibians and Reptiles of Costa Rica: A Herpetofauna Between Two Continents, Between Two Seas. Univ. Chicago Press, Chicago, Illinois. 934 pp.). Five *A. altae* (mean SVL = 45.2 mm ± 1.6 SD, range: 44–48 mm) collected November 1963 and deposited in the herpetology collection of the Natural History Museum of Los Angeles County (LACM), Los Angeles, California, USA were examined for helminths (Costa Rica: Cartago Province, LACM 149056, 149063–149065, 169075).

The digestive tract was removed through a mid-ventral incision, and the esophagus, stomach and small and large intestines were examined for helminths under a dissecting microscope. Cestodes were found in the small intestine, nematodes were found in the small and large intestines. Cestodes were regressively stained in hematoxylin, dehydrated in ethanol and mounted in Canada balsam; nematodes were cleared in glycerol and cover-slipped on a microscope slide. Both preparations were studied under a compound microscope. The cestodes were identified as *Mathevotaenia panamaensis* (prevalence [number infected lizards/number lizards examined × 100] = 40%, mean intensity [mean number helminths per infected lizard ± 1 SD] = 36.0 ± 39.6, range: 8–64). The nematodes were identified as *Falcaustra costaricae* (prevalence = 40%, mean = 1.0). Helminths were deposited in the United States National Parasite Collection (USNPC), Beltsville, Maryland: *Mathevotaenia panamaensis* (USNPC 103944); *Falcaustra costaricae* (USNPC 103945).

Mathevotaenia panamaensis was recently described from *Sceloporus malachiticus* from Panama by Bursey et al. (2010. Acta Parasitol. 55:53–57). *Anolis altae* is the second host to harbor this parasite although an unidentified species of *Mathevotaenia* was found in *Anolis humilis* from Nicaragua (Goldberg et al. 2010. Comp. Parasitol. 77:242–246). *Mathevotaenia panamaensis*, a member of the Anoplocephalidae, utilizes an arthropod as an intermediate host (Roberts and Janovy 2005. Gerald D. Schmidt

& Larry S. Roberts' Foundations of Parasitology, McGraw Hill Higher Education, Boston, Massachusetts. 702 pp.). *Falcaustra costaricae* was described from *Anolis* (as *Norops*) *tropidolepis* from Costa Rica (Bursey et al. 2004. J. Parasitol. 90:598–603). It has been reported from anurans (Goldberg and Bursey 2010. J. Nat. Hist. 44:1755–1787) and *Anolis lionotus* from Costa Rica (Bursey and Brooks 2010. Comp. Parasitol. 77:232–235). The life cycle of *Falcaustra costaricae* is unknown, but it is thought that larvae may utilize invertebrates as paratenic (= transport) hosts which are infective upon ingestion by lizards (Anderson 2000. Nematode Parasites of Vertebrates: Their Development and Transmission. CABI Publishing, Oxon, UK. 650 pp.). *Anolis altae* represents a new host record for *M. panamaensis* and *F. costaricae*. Costa Rica is a new locality record for *M. panamaensis*.

We thank C. Thacker (LACM) for permission to examine *A. altae* which are part of the Costa Rica Expeditions Collection donated to LACM by J. M. Savage in 1998.

STEPHEN R. GOLDBERG, Whittier College, Department of Biology, Whittier, California 90608, USA (e-mail: sgoldberg@whittier.edu); **CHARLES R. BURSEY**, Pennsylvania State University, Shenango Campus, Department of Biology, Sharon, Pennsylvania 16146, USA (e-mail: cxb13@psu.edu).

***ANOLIS CYBOTES CYBOTES* (Hispaniolan Stout Anole) and *ANOLIS MARRON* (Jacmel Gracile Anole). PREDATION/PREY.** On 18 August 2009, at approximately 1400 h, while sampling anoles at a coastal locality near Marigot, Haiti (approximately 20 km E of Jacmel), we encountered a large adult male *Anolis c. cybotes* vertically perched with its head pointing upwards on the trunk of a coconut palm with the hindquarters of an adult female *A. marron* protruding from its mouth (Fig. 1). The *A. c. cybotes* held its ground as we moved around it and photographed it *in situ*, at one point partially extending its dewlap and doing a pushup. After photographing the *A. c. cybotes* with its prey we captured it using a noose and placed it in a cloth bag, which we subsequently stored in an empty plastic cooler inside an air-conditioned car for the remainder of the day. At some point during capture of the *A. c. cybotes*, the *A. marron* autotomized its tail, which we were not able to locate. At 2230 h (8.5 h after discovery and capture), the *A. c. cybotes* still had not fully swallowed the *A. marron* and the feet of the prey continued to protrude from its mouth. At this time, we euthanized the *A. c. cybotes*, extracted the *A. marron*, and measured, photographed, and preserved both specimens (Fig. 2). The *A. c. cybotes* measured 70 mm SVL and weighed 9.0 g. The *A. marron* measured 45 mm SVL and weighed 2.4 g. The predated anole was intact, but partially digested externally when removed from the stomach of its predator. The skin on the anterior half of the anole had been largely digested, and the skull and forelimbs of the anole showed considerable loss of structural integrity.

Although the conditions of its captivity were artificial, the fact that this large male *A. c. cybotes* failed to fully ingest the *A. marron* prey item over an 8.5 h period, and the fact that considerable digestion of the anterior portion of the *A. marron* took place over this period suggests that (1) this prey item was close to the maximum size possible for this anole, and (2) that *A. c. cybotes* may occasionally capture and eventually consume prey items that it may not fully ingest upon capture. It is possible that the progress of ingestion was correlated with the progress of digestion of the prey's anterior portion. However, it is also possible

FIG. 1. Male *Anolis cybotes cybotes* with female *A. marron* protruding from its mouth, photographed *in situ* immediately after discovery.

COLOR REPRODUCTION SUPPORTED BY THE THOMAS BEAUVAIS FUND

that these observations largely reflect the influence of the capture and containment of the predator. The *A. c. cybotes* was kept inactive at a slightly lower temperature than it was captured at, so we urge caution in interpreting its rate of digestion following capture.

Although intraguild predation events have been reported several times in *Anolis*, the sizes of the anoles involved have rarely been measured quantitatively (Gerber 1999. *Anolis* Newsletter V:28–39). This event is noteworthy in that the predator consumed a congener measuring 64.3% of its own SVL and approximately26.7% of its own body weight (possibly more, given the lost tail and partial digestion of the *A. marron* specimen at the time of measurement). To our knowledge, this is the highest

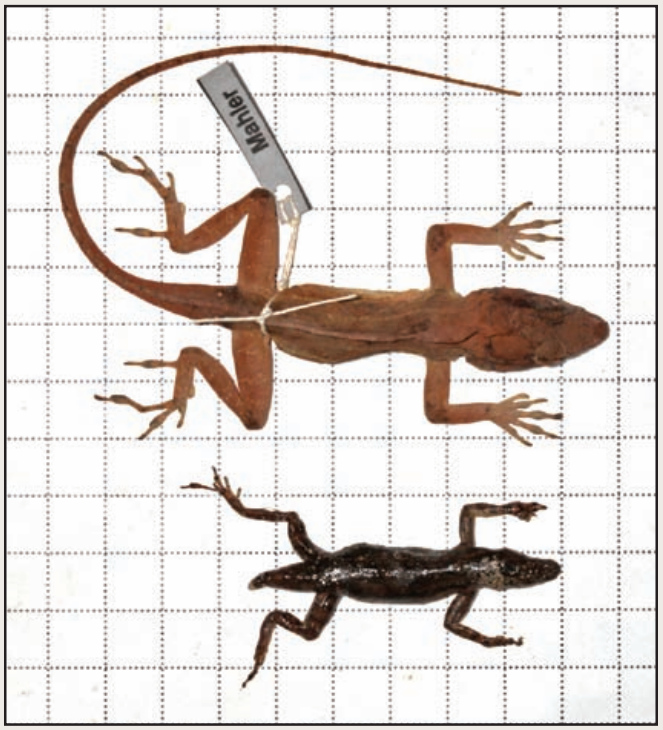

FIG. 2. Male *Anolis cybotes cybotes* (top) and female *A. marron* (bottom), immediately after the latter was extracted from the stomach and mouth of the former, but after at least 8.5 h of digestion. Grid unit = 1 cm.

prey:predator ratio quantified for anoles (Gerber 1999, *op. cit.*; Losos 2009. Lizards in an Evolutionary Tree. Univ. of California Press, California. 507 pp.). In experiments, *A. cybotes* is known to feed on juveniles of other anole species (e.g., *A. bahorucoensis*, *A. coelestinus*, and *A. distichus*), as well as juvenile *A. cybotes* (Fitch and Henderson 1987. Amphibia-Reptilia 8:69–80). Although previous natural predation of *A. cybotes* on *A. marron* has not been reported, *A. cybotes* has been documented to predate on a species closely related to *A. marron*, *A. distichus*. *Anolis marron* coexists with *A. cybotes* throughout the former species' entire range, and these two species clearly compete, often using the same food resources on a single tree (pers. obs.). This observation demonstrates that these two species interact as predator and prey as well as resource competitors.

These specimens are deposited in the Museum of Comparative Zoology at Harvard University (*A. c. cybotes* = MCZ R-188077; *A. marron* = MCZ R-188078).

***ANOLIS EQUESTRIS* (Knight Anole). REPRODUCTION.** *Anolis equestris* is native to Cuba and has been introduced to Florida and Oahu, Hawaii (Henderson and Powell 2009. Natural History of West Indian Reptiles and Amphibians. Univ. Press Florida, Gainesville. 495 pp.). Anecdotal information on reproduction is in Henderson and Powell (*op. cit.*), from Florida (Meshaka et al. 2004. The Exotic Amphibians and Reptiles of Florida. Krieger Publ. Co., Malabar, Florida. 155 pp.; Meshaka and Rice 2005. *In* Meshaka and Babbitt [eds.], Amphibians and Reptiles Status and Conservation in Florida, pp. 225–230. Krieger Publ. Co., Malabar, Florida) and Hawaii (McKeown 1996. A Field Guide to Reptiles and Amphibians in the Hawaiian Islands. Diamond Head Publishing, Los Osos, California. 172 pp.). *Anolis equestris* was first noted in Oahu in 1981 (McKeown, *op. cit.*). The purpose of this note is to add to the knowledge on *A. equestris* reproduction from a histological examination of gonadal material from Hawaii.

A sample of 17 *A. equestris* from Oahu, Hawaii consisting of 10 adult males (mean SVL = 148.4 mm ± 4.1 SD, range: 115–157 mm), five adult females (mean SVL = 143.4 mm ± 3.9 SD, range: 140–148 mm), and two subadult females (mean SVL = 108.0 mm ± 31.8 SD, range: 85–130 mm) from Oahu, Hawaii was examined from the Bishop Museum (BPBM), Honolulu, Hawaii, USA: BPBM:11805, 12200, 12201, 12209, 13718, 14163, 14821, 14822, 14998, 16960, 16961, 20982, 20983, 25352, 31892, 31893, 33835. *Anolis equestris* were collected 1993 to 2009.

An incision was made on the lower left lateral side of the abdomen to expose the gonads. The left testis was removed from males and the left ovary was removed from females for histological examination. Oviductal eggs and enlarged follicles (> 4 mm) were counted. Tissues were embedded in paraffin; sections were cut at 5 µm and stained with hematoxylin followed by eosin counterstain. Histology slides are deposited in BPBM.

The only stage observed in the testicular cycle was spermiogenesis in which the lumina of the seminiferous tubules were lined by sperm or clusters of metamorphosing spermatids. Males undergoing spermiogenesis were found in the following months (sample size in parentheses): February (N = 2); April (N = 2); May (N = 4); July (N = 1); August (N = 1), indicating a prolonged period of spermiogenesis. The smallest reproductively active male (BPBM 14163) measured 115 mm SVL and was from May. The smallest reproductively active female (BPBM 16961) measured 140 mm SVL and was from April. Three adult females from April each contained oviductal eggs. In one, (BPBM 12200) the eggs were fused and could not be counted. The other two females contained evidence that consecutive clutches are produced as one of them (BPBM 11805) contained one oviductal egg and two follicles (> 4 mm) in both the right and left ovaries and the other (BPBM 16961) contained both one oviductal egg and one enlarging follicle (> 4 mm). *Anolis equestris* produces clutches of one to two eggs (Haselhaus and Schmidt 1995. Caribbean Anoles. T.F.H. Publ., Neptune City, New Jersey. 64 pp.). Two females (BPBM 20982, 20983) from December contained quiescent ovaries (no yolk deposition) suggesting some seasonality in the ovarian cycle of *A. equestris* in Hawaii.

I thank Pumehana Igada (BPBM) for facilitating my examination of *A. equestris*.

STEPHEN R. GOLDBERG, Department of Biology, Whittier College, Whittier, California 90608, USA; e-mail: sgoldberg@whittier.edu.

***CTENOSAURA OEDIRHINA* (Roatán Spiny-tailed Iguana). SAUROPHAGY.** Here we report an instance of saurophagy by *Ctenosaura oedirhina* at Arch's Iguana Farm, French Harbour, Roatán, Honduras (16.3575°N, 86.441111°W). The farm is a rehabilitation center for *Iguana iguana* (Green Iguana). The *Iguana iguana* are free roaming but at an artificially high density. Wild *C. oedirhina* also occur at this site as it falls within their natural distribution, however this species is present in much lower numbers.

At ~1125 h on 17 August 2008 we observed an adult *Ctenosaura oedirhina* actively pursue and consume a juvenile *Iguana iguana*. The *I. iguana* was caught by the posterior region of its torso after a short chase, and after some maneuvering the *Ctenosaura* proceeded to swallow the *Iguana* whole from the rear. The entire predation event was very rapid, lasting only approximately three minutes from the initiation of the chase to complete ingestion.

To our knowledge this is the first account of saurophagy in *Ctenosaura oedirhina*. This is a relatively under-studied iguanid species, with very few reports concerning its dietary preferences. The most reliable of available accounts is found in the proposal for the inclusion of this species into CITES Appendix II (reference number CoP15 Prop. 11), where *Ctenosaura oedirhina* was "assumed to be mainly herbivorous and to feed opportunistically on small invertebrates."

It is possible that this predation was a unique event triggered by the artificially high density of *Iguana iguana* at this site. However, given that other closely related species of *Ctenosaura* have been documented to include saurian prey in their diet, with saurophagy observed in both *C. bakeri* (Dirksen and Gutsche 2006. Elaphe 14:51–52) and in *C. similis* (Henderson 1973. J.Herpetol. 7:27–33), it seems likely that this type of predation event might be more commonplace than is currently accredited to this genus.

Further study would be required to elucidate whether this observation represents an isolated opportunistic predation event or whether saurian prey comprise a regular part of the natural diet of *C. oedirhina*.

CATRIONA HENDRY (e-mail: cathendry2@hotmail.com) and **ROBERT GANDOLA**, 27 Ayrfield Park, Dublin 13, Dublin, Republic of Ireland.

***CYCLURA CYCHLURA INORNATA* (Allen Cays Rock Iguana). MORTALITY.** Ingestion of unnatural or atypical food items (especially human-produced refuse) by reptiles in nature can have significant negative consequences (Mrosovsky et al. 2010. Mar. Pollution Bull. 58:287–289). Here we report the apparent death of a *Cyclura cychlura inornata* following the ingestion of a marine sponge (Porifera). On 18 May 2009, a marked female (15.7 years old; SVL ca. 28 cm) in a long-term study (Iverson et al. 2006. Biol. Cons. 132:300–310) was found dead and nearly mummified along the southwest coastline of Leaf Cay in the Allen Cays in the northern Exuma Islands (site detailed in Iverson et al. 2004. Herpetol. Monogr. 18:1–36). Although the carcass was nearly completely intact, detritivores had partially opened the ventral body wall, exposing the contents of her abdomen. The internal organs were mostly gone, but the space was completely filled with a large piece of dried marine sponge (ca. 4 cm × 2 cm × 1.5 cm; Fig. 1). It appeared that she had ingested the large sponge, but that it had obstructed her gastrointestinal tract, causing her death. Whether she ingested the sponge during natural foraging, or during a tourist feeding event on the nearby landing beach is unknown. For example, on 25 May 2009 one of us (CRK) observed an Exuma Islands Iguana (*Cyclura cychlura figginsi*) on Bitter Guana Cay in the central Exuma Islands foraging at the high tide line, and ingesting a small piece of marine sponge by its own choice (Fig. 2). In addition, we regularly observe both subspecies of iguana in the Exumas foraging among the wrack at the high tide line. However, we have also observed tourists throwing litter and beach wrack (from seaweed to sticks to dead sponges) toward iguanas almost daily on the Leaf Cay beach to induce them to come to feed. More specifically, we have occasionally observed the ingestion of sponges by Allen Cays Iguanas under these conditions. Our observations suggest that although dead sponges may occasionally be part of the natural diet of these iguanas, they may sometimes be hazardous to the iguana's health.

FIG. 1. Mummified carcass of Allen Cays Iguana that apparently died because of ingestion of a marine sponge.

FIG. 2. Exuma Island Iguana foraging on a marine sponge at high tide line.

***HEMIDACTYLUS AGRIUS* (Country Leaf-toed Gecko). REPRODUCTION.** Communal nesting has been recorded in several species of lizards, including the families Teiidae (Magnusson and Lima 1984. J. Herpetol. 18:73–75), Polychrotidae (Rand 1967. Herpetologica 23:227–230; Estrada 1987. Poeyana 353:1–9), and,

in particular, Gekkonidae (Rand, *op. cit.*; Greer 1967. Breviora 268:1–19; Vitt et al. 1997. Copeia 1997:32–43). Rand (1967, *op. cit.*) suggested two possible explanations for communal egg laying: the attractiveness of sites suitable for oviposition and the relative scarcity of suitable places to spawn.

Communal nests have been found in litter, logs and fallen branches on the ground, holes in logs, termite mounds, rocky pools, anthropogenic debris and buildings, among others (Greer, *op. cit.*; Rand, *op. cit.*; Krysko et al. 2003. Amphibia-Reptilia 24:390–396). The genus *Hemidactylus* is characterized by oviposition of one or two eggs (Krysko et al., *op. cit.*). Herein we present a new record of communal nesting by *Hemidactylus agrius*. Little is known about this gecko's ecology and the data presented here contribute to the knowledge of the reproductive biology of this species.

On 26 September 2009, during field research in a semiarid area at the Fazenda Experimental Vale do Curu, near Pentecoste municipality, State of Ceará, Brazil (3.82145°S, 39.33824°W; datum WGS 84), we found a nest with five eggs of *Hemidactylus agrius*. The eggs were found aggregated and juxtaposed to one another, oviposited at ground level in a small brick house.

The eggs were handled carefully and taken to the laboratory of herpetology at the Núcleo Regional de Ofiologia da UFC (NUROF – UFC), where they were monitored until hatching so the identification of the species could be determined. Hatching occurred from 11–16 November 2009. Hatchling voucher specimens were placed in the Coleção Herpetológica da UFC – CHUFC (L 4105, L 4106, L 4107, L 4108 and L 4109).

Based on the number of eggs and hatching dates, we believe at least three females participated in oviposition at the nest. To our knowledge, this is the first known occurrence of communal egg laying in *H. agrius*.

***HEMIDACTYLUS BROOKII* (Brook's Gecko). AVIAN PREDATION.** *Hemidactylus brookii* is one of the most common gekkonids in the Indian subcontinent (Smith 1943. The Fauna of British India, including Ceylon and Burma. Reptilia and Amphibia. Vol. III. Serpentes. Taylor and Francis, London. xii + 583 pp.; Daniel 2002. The Book of Indian Reptiles and Amphibians. Bombay Natural History Society. Oxford University Press; Sharma 2002. The Fauna of India and the Adjacent Countries–Reptilia (Sauria) Volume II, pp. 107–108. Director, Zoological Survey of India, Kolkata). *Hemidactylus brookii* is a crepuscular and nocturnal species. It occurs in many different habitats such as rocky areas and grassy plains. Despite its abundance and wide distribution, little is known about the ecology of this species or its natural predators. Here we report on the predation of this gecko by the Oriental Magpie Robin (*Copsychus saularis*), a typically insectivorous and diurnal forest bird.

On 31 July 2010 at 1715 h, we photographed an adult male *C. saularis* in Jiwaji University campus, Gwalior, Madhya Pradesh, India (26.63278°N, 77.864167°E; 119 m elev.) consuming an adult *H. brookii* after killing it by beating it several times on the forest floor (Fig. 1). The bird then consumed the lizard in small pieces.

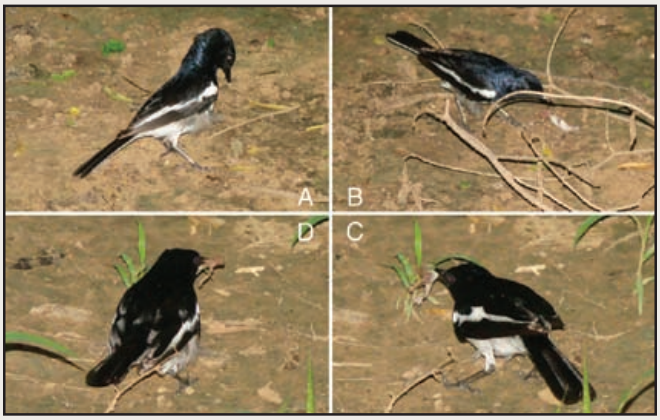

PHOTO BY VIVEK SHARMA

FIG. 1. The progressive steps (A, B, C, and D) of predation on *Hemidactylus brookii* by *Copsychus saularis*.

The Oriental Magpie Robin typically feeds on insects (Kazmierczak and Perlo 2006. A Field Guide to the Birds of India. Om Book Services, New Delhi, India. pp. 264). Our observations are the first photographic evidence of predation by this bird on a lizard. This note is of further interest as it reports a diurnal predator consuming a nocturnal prey species.

This research was supported by the financial assistance from the Department of Science and Technology, New Delhi, India.

KRISHAN KUMAR SHARMA (e-mail: kksmds@gmail.com), **VIVEK SHARMA** (e-mail: vivekherps@gmail.com), Laboratory of Biodiversity and Molecular Developmental Biology, Department of Zoology, Maharshi Dayanand Saraswati University, Ajmer 305 009, Rajasthan, India; **HARI SINGH**, School of Studies in Zoology, Jiwaji University, Gwalior, Madhya Pradesh, India (e-mail: hsingh7wild@gmail.com).

***LYGODACTYLUS KLUGEI* (NCN). SEXUAL DIMORPHISM, HABITAT, DIET.** *Lygodactylus klugei* is a small-bodied, diurnal and arboreal gecko from the caatinga of northern South America. Here we provide data on sexual dimorphism, habitat use, and diet of *L. klugei* from the northernmost caatinga of Brazil. We captured 22 adults (11 males and 11 females) from 16 February to 3 March, 2010 at the Fazenda Experimental do Vale do Curu (FEVC), Pentecoste Municipality, Ceará State, Brazil (03.42°S, 39.33°W). We recorded perch height (PH) and perch circumference (PC) from the place each lizard was first sighted. In the lab, lizards were euthanized with an injection of sodium thiopental (Tiopental®) and fixed with 10% formalin. Next, we measured snout–vent length (SVL) and determined sex via inspection of gonads. Diet was determined by inspection of stomach contents (to taxonomic order for insects), and the volume of prey estimated by using the formula for a prolate spheroid. Diet niche breadth was calculated following Pianka (1973. Ann. Rev. Ecol. Syst. 4:53–74). We also calculated the standardized diet niche breadth by dividing the niche breadth value by the total number of prey categories, which allows for comparisons with other studies.

Males were smaller than females in SVL: males = 26.4 ± 1.6 mm, females = 28.4 ± 0.9 mm (*t*-test: $t = 3.51$, $P = 0.002$), as was found for *L. klugei* from Exu, Pernambuco, Brazil (Vitt 1986. Copeia 1986:773–786). All lizards were found on tree trunks. Neither PH nor PC differed between the sexes: PH males = 30 cm, females = 37.5 cm (Mann–Whitney *U*: 11, $P = 0.46$); PC males = 34.3 ± 13.9, females = 29.7 ± 7.8 cm (*t*-test: –0.91 P 0.37). At FEVC, stomach contents included six types of prey (Araneae, Coleoptera,

Diptera, Hemiptera, Hymenoptera, and insect larvae). Coleopterans were the most prevalent prey item found in stomachs (89%), representing 55% of the total numerical prey frequency, followed by dipterans (22%). Volumetrically, coleopterans represented 48% and hymenopterans 28% of the prey eaten. Food niche breadth was 2.94 and standardized niche breadth was 0.49. Prey volume was not related to lizard SVL or to head width (all variables $\log_{10}$ transformed).

Lygodactylus klugei from FEVC seem to eat a relatively narrow range of prey with coleopterans and hemipterans accounting for the majority of the total prey volume. Vitt (1995. Occas. Pap. Oklahoma Mus. Nat. Hist. 1:1–29) found that *L. klugei* from Exu, Pernambuco, Brazil ate 25 prey types, but mainly termites and spiders. Diet niche breadth for *L. klugei* from Vitt's (1995, *op. cit.*) study was 8.33 (standardize niche breadth = 0.24). Thus, *L. klugei* from FEVC, despite the inclusion of fewer prey types, seems to exploit food resources more equitably compared to the population from Exu.

We are grateful to the administrative staff of the Fazenda Experimental do Vale do Curu for logistical support. We also thank R. Espinoza for reviewing this note. CABG benefitted from a grant from Conselho Nacional de Desenvolvimento Científico e Tecnológico proc. 35.0241/2008-2 and DZ received a grant from Fundação Cearense de Apoio ao Desenvlvimento Científico e Tecnológico BMD-0008-00060.01.14/10. The study was conducted under Instituto Chico Mendes de Conservação da Biodiversidade (ICMBio) permit 21551-1.

***MABUYA DORSIVITTATA* (NCN). REPRODUCTION.** *Mabuya dorsivittata* is a viviparous scincid with a relatively wide geographical distribution in South America. The only available data on reproduction were based on a few specimens from a population in southeastern Brazil (Vrcibradic et al. 2004. Herpetol. J. 14:109–112). Here we expand upon the knowledge of the reproductive biology of this species.

A mark-recapture study was conducted from February 2001 to January 2004 using pitfall traps with drift-fencing in Santa Maria, Rio Grande do Sul, Brazil. In February 2001, a gravid female *Mabuya dorsivittata* was captured, measuring 65.21 mm snout–vent length (SVL); 129.31 mm tail length (TL), and weighed 4 g. Five young were born the same day of capture; two females and three males, all with the same weight (0.75 g). Measurements ranged from 29.07–32.26 mm SVL (mean = 31.8 ± 1.4) and 40.45 to 55.27 mm (TL) (mean = 46.6 ± 5.6). The neonate skinks were released three days after birth near the capture location of the mother, but none was recaptured until January 2004. The mother was recaptured only once, 10 months later, non-gravid. The brood size we report here differs from that recorded from southeast Brazil: 3.2 ± 0.45 embryos (Vrcibradic et al. 2004, *op. cit.*). This report is important for future studies on the reproductive aspects of *M. dorsivittata*, as only limited data on this species are available.

***PLESTIODON OBSOLETUS* (Great Plains Skink). LIFE HISTORY.** Herein we report information on habitat, morphology, and activity from 813 captures of 505 individual *Plestiodon obsoletus* from riparian forest habitat along the middle Rio Grande in central New Mexico. We used toe-clipping during a mark-recapture study conducted from late May to mid-September each year from 2000 to 2006 to evaluate the effects of non-native plant and fuels removal on herpetofauna (Bateman et al. 2008. Restoration Ecol. 16:180–190). We monitored herpetofauna at 12 sites spanning 140 km of river from Albuquerque (35.008380°N, 106.681805°W) to Bosque del Apache National Wildlife Refuge (33.805122°N, 106.859980°W). The climate is semiarid to arid (Tuan 1962. Annals Assoc. Amer. Geograph. 52:51–68). Trapping arrays were located in riparian forests containing a mixture of native Rio Grande Cottonwood (*Populus deltoides wislizenii*) and willow (*Salix* spp.), and non-native plants, including saltcedar (*Tamarix chinensis* and *T. ramosissima*) and Russian Olive (*Elaeagnus angustifolia*).

Plestiodon obsoletus were captured by means of pitfall (5-gallon, 18.9 liter buckets) and funnel traps, 55% and 45%, respectively. Snout–vent length (SVL), vent–tail length (VTL), and mass were measured (Table 1). Sex was often difficult to determine and was confirmed only when experienced technicians were available. Skink hatchlings became active in July and captures peaked during the first half of August. For example, of the number of hatchlings captured for the first time, 3.2% (mean SVL = 38.4 mm, range = 36–41 mm, N = 7) occurred from 1–15 July, 32.7% (mean SVL = 37.9 mm, range = 31–64 mm, N = 72) from 16–31 July, 36.4% (mean SVL = 38.0 mm, range = 34–45 mm, N = 80) from 1–15 August, 23.2% (mean SVL = 40.8 mm, range = 36–58 mm, N = 51) from 16–31 August, and 4.5% (mean SVL = 48.2 mm, range = 38–58 mm, N = 10) from 1–15 September. Adult activity, in terms of total captures, peaked in the latter half of July. For example, of total number of adult captures, 7.5% (mean SVL = 91.7 mm, range = 63–111 mm, N = 39) occurred from 1–15 June, 20.0% (mean SVL = 93.7 mm, range = 61–115 mm, N = 104) from 16–30 June, 19.0% (mean SVL = 88.8 mm, range = 60–113 mm, N = 99) from 1–15 July, 23.5% (mean SVL = 89.1 mm, range = 63–124 mm, N = 122) from 16–31 July, 16.5% (mean SVL = 91.0 mm, range = 68–120 mm, N = 86) from 1–15 August, 10.4% (mean SVL = 87.6 mm, range = 67–120 mm, N = 54) from 16–31 August, and 3.1% (mean SVL = 88.6 mm, range = 71–117 mm, N = 16) from 1–15 September. Only 22% (114 of 505) of marked skinks were recaptured and most sightings occurred during the summer of marking, although some skinks were seen up to three summers later. For example, 25 skinks were recaptured the summer following first capture, 9 were recaptured two summers later, and 5 were recaptured three summers later. From these data, we documented that skinks grew the fastest in their first year and that growth slowed as skinks reached adult size. For example, skinks first encountered as hatchlings and recaptured the following summer grew by 60% in SVL (mean first summer SVL =

TABLE 1. Morphological characteristics of *Plestiodon obsoletus* captured during 2000–2006 from the riparian forest along the middle Rio Grande in central New Mexico. Data are summarized by captures of individuals < 5 g mass (hatchlings) and > 5 g mass (juveniles and adults). Data represent captures and individuals occur more than once in table.

	Hatchling (< 5 g)				Juvenile, Adult (> 5g)			
Sex	Number of captures	Mean SVL (mm)	Mean VTL (mm)	Mean Mass (g)	Number of captures	Mean SVL (mm)	Mean VTL (mm)	Mean Mass (g)
Female	6	44.3 (± 3.70)	53.8 (± 2.09)	2.2 (± 0.56)	129	88.2 (± 1.08)	120.2 (± 3.01)	16.8 (± 0.63)
Male	5	42.6 (± 2.82)	56.4 (± 5.78)	1.3 (± 0.34)	52	92.5 (± 1.89)	123.9(± 4.53)	19.5 (± 1.22)
Unknown	236	39.5 (± 0.32)	49.8 (± 0.93)	1.2 (± 0.05)	340	90.7 (± 0.60)	123.3 (± 1.68)	16.9 (± 0.36)

44.2 mm, range = 41–48 and one year SVL = 70.8 mm, range = 51–83, N = 10). Whereas skinks first encountered as adults and recaptured the following summer grew only 10% in SVL (mean first summer SVL = 88.6 mm, range = 63–113, and the following year SVL = 97.4 mm, range = 80–109, N = 19). We documented similar hatchling period and SVL compared to other locations in New Mexico (Belfit and Belfit 1985. Southwest. Nat. 30:612–614) and in Kansas (Hall and Fitch 1971. Kansas Acad. Sci. 74:93–98). However, this report summarizes lesser known growth rates for *Plestiodon obsoletus* tracked over time in a field setting.

The Middle Rio Grande Conservancy District, Bosque del Apache National Wildlife Refuge, and Albuquerque Open Space permitted access to study sites. The University of New Mexico Animal Care and Use Committee approved field techniques (protocol #20415). This study was funded by the USDA Forest Service – RMRS Middle Rio Grande Ecosystem Management Unit, Joint Fire Sciences Program, National Fire Plan, US FWS Bosque Improvement Initiative, and USFS S&PF NM Collaborative Forest Restoration Program. This note was improved by helpful suggestions by James M. Walker.

***POLYCHRUS GUTTEROSUS* (Berthold's Bush Anole). ENDOPARASITES.** *Polychrus gutterosus* occurs in lowland and lower premontane evergreen forests from northwestern Honduras and western Costa Rica to northwestern Ecuador at 6–700 m elevation (Savage 2002. The Amphibians and Reptiles of Costa Rica: A Herpetofauna Between Two Continents, Between Two Seas. University of Chicago Press, Chicago, Illinois. 934 pp.). To our knowledge there is one report of helminths from *P. gutterosus*; Bursey et al. (2007. Comp. Parasitol. 74:108–140) reported one species of trematode, *Parallopharynx arctus*, and two species of nematodes, adults of *Physaloptera retusa* and larvae of *Ophidascaris* sp., from *P. gutterosus* collected in Panama. The purpose of this note is to add new records to the helminth list for *P. gutterosus* collected in Costa Rica as part of an ongoing study of the biodiversity of helminths of amphibians and reptiles from Central America.

Three *P. gutterosus* (mean SVL = 141.7 mm ± 49.1 SD, range: 85–170 mm) deposited in the herpetology collection of the Natural History Museum of Los Angeles County (LACM), Los Angeles, California from Costa Rica were examined: LACM 166772, from Heredia Province, collected December 1973; LACM 166773, from Alajuela Province, collected March 1966; LACM 166776, from Puntarenas Province, collected October 1974.

The body cavity was opened by a mid-ventral incision and the digestive tract was removed and opened. The esophagus, stomach and small and large intestines were examined for helminths. Only LACM 166772 contained helminths. Five digeneans were found in the small intestines (prevalence = number infected lizards/all lizards examined × 100 = 33%); mean = 5.0. One nematode (prevalence = 33%; mean = 1.0) was found in the large intestines. The digeneans were regressively stained in hematoxylin, mounted in Canada balsam, studied as whole mounts under a compound microscope and identified as *Mesocoelium monas*. The nematode was cleared in a drop of glycerol on a microscope slide, cover-slipped, studied under a compound microscope and identified as *Strongyluris panamaensis*. Voucher helminths were deposited in the United States National Parasite Collection (USNPC), Beltsville, Maryland, USA as *Mesocoelium monas* (USNPC 104037); *Strongyluris panamaensis* (USNPC 104038).

Mesocoelium monas is cosmopolitan in distribution and is known from a large number of hosts (Goldberg et al. 2009. Comp. Parasitol. 76:58–83). Infection occurs with the ingestion of an infected snail or vegetation supporting cysts (Thomas 1965. J. Zool. 146:413–446). *Strongyluris panamaensis* was described from *Anolis biporcatus* from Panama (Bursey et al. 2003. J. Parasitol. 89:118–123). It has also been reported in *Anolis* (as *Norops*) *limifrons* (Bursey and Goldberg 2003. J. Parasitol. 89:573–576), *Ctenosaura quinquecarinata*, and *Sceloporus variabilis* from Costa Rica (Bursey and Brooks 2010. Comp. Parasitol. 77:232–235). *Strongyluris panamaensis* is a member of the Heterakidae which do not utilize intermediate hosts in their life cycle (Anderson 2000. Nematode Parasites of Vertebrates. Their Development and Transmission. CABI Publ. Oxon, UK. 650 pp.). Lizards likely become infected when they ingest contaminated substrate while feeding. *Polychrus gutterosus* represents a new host record for *Mesocoelium monas* as well as *Strongyluris panamaensis*.

We thank C. Thacker (LACM) for permission to examine *P. gutterosus*, part of the Costa Rica Expeditions Collection donated to LACM in 1998 by J. M. Savage. Daisy Salguero (Whittier College) assisted with dissections.

***RIAMA OCULATA* (NCN). PREHENSILE TAIL and NEW HABITAT TYPE.** The presence of prehensile tails or other arboreal

FIG. 1. *Riama oculata* demonstrating use of prehensile tail on first author's finger.

characteristics have not previously been documented in the semi-fossorial gymnophthalmnid genus *Riama* (Reyes-Puig 2008. Check List 4:366–372) and although there is no specific information on habitat preferences, all reports indicate capture in forested environments. *Riama oculata* is commonly encountered in the Santa Lucía Cloud Forest Reserve, Nanegal, Pichincha, Ecuador, with primary capture through the use of pitfall traps with drift fences (Maddock et al., unpubl. data). Here we present evidence of a prehensile tail in an individual *R. oculata* upon capture.

At 1550 h on 19 July 2010 an adult *R. oculata* was captured by hand as it moved along the ground inside the sugarcane plantation at the Santa Lucía Cloud Forest Reserve (00.11819°N, 078.60915°W; WGS 84). Upon capture the specimen wrapped its tail securely around the left index finger of its captor; the other hand was slowly moved away and the *R. oculata* remained attached hanging by its tail (Fig. 1). After examination in the field, the specimen was released back to the original location of capture.

These observations, including the presence of this species in a novel agricultural habitat and a prehensile tail, are new records for this poorly studied species and therefore increase knowledge of its natural history and behavior.

We thank Earthwatch Institute for funding our fieldwork, and the staff at the Santa Lucía Cloud Forest Reserve and Earthwatch volunteers for their support and help. We also thank David Kizirian for encouraging us to publish the findings presented herein and Wolfgang Wüster for editing the figure for publication.

FIG. 1. *Riama unicolor* with autotomized tail emerging from stomach following specimen examination.

***RIAMA UNICOLOR* (NCN). FEEDING and NEW ALTITUDINAL RANGE.** *Riama unicolor* is a small, semi-fossorial gymnophthalmnid found on the Pacific versant cloud forests of northwestern Ecuador between 2390–3300 m (Copping 1957. Brit. J. Herpetol. 2:54–56; Kizirian 1996. Herpetol. Monogr. 10:85–155). This species is known to prey on small invertebrates and maggots, although this information is based only on captive observations (Kizirian 1996, *op. cit.*). Here we report on an observation of *R. unicolor* consuming its recently autotomized tail and provide new data on the altitudinal range for the species.

At 1346 h on 1 July 2010 a *Riama unicolor* (SVL = 8.8 mm; weight = 1 g) was captured just below the surface of the ground by excavation at the Santa Lucia Community Reserve, Nanegal, Pichincha, Ecuador (0.11266°N, 78.61143°W; 1775 m elev.). Upon capture the specimen autotomized part of its tail (5.3 mm in length). Both the lizard and its tail were stored in a field container together until the following day. On the morning of 2 July 2010 the specimen was found dead in the container. Tissue was taken from the liver for future DNA analyses and upon inspection the tail was discovered inside the lizard's stomach (Fig. 1). The specimen was deposited at the Museo de Zoología QCAZ, Pontificia Universidad Católica del Ecuador (SC 32463).

This report increases our knowledge of this poorly understood species, extending its range down to altitudes as low as 1775 m and documenting a novel observation on its feeding behavior.

We thank Earthwatch Institute for funding our fieldwork, and all of the staff at Santa Lucia Community Reserve and Earthwatch volunteers for their support and help. We also thank Wolfgang Wüster for helping with image editing for publication.

***SCELOPORUS ORCUTTI* (Granite Spiny Lizard). MINIMUM SIZE AT REPRODUCTION.** *Sceloporus orcutti* ranges from the lower slopes of the Peninsular Range of southern California south to just north of the Cape of Baja California (Stebbins 2003. A Field Guide to Western Reptiles and Amphibians. Houghton Mifflin Co., Boston, Massachusetts. 533 pp.). Reproduction of *S. orcutti* in California is known from a study by Mayhew (1963.

Copeia 1963:144–152) on a population in Riverside Co. The purpose of this note is to report *S. orcutti* reaches reproductive maturity at smaller sizes in Baja California Sur, Mexico, when compared to the southern California population.

Twenty males (mean SVL = 82.8 mm ± 10.4 SD, range = 67–96 mm) and four females (mean = 71.2 mm ± 9.0 SD, range = 63–84 mm) from Baja California Sur were examined from the herpetology collection of the Natural History Museum of Los Angeles County (LACM), Los Angeles, California: LACM 97335, 97336, 128068–128089. Lizards were collected in 1967, 1975, and 1978. A small slit was made in the lower part of the abdomen and the left gonad was removed for histological examination. Gonads were embedded in paraffin and histology slides were cut at 5µm and stained by hematoxylin followed by eosin counterstain. Enlarged follicles (> 4 mm) or oviductal eggs were counted. Histology slides were deposited in LACM.

Mayhew (*op. cit.*) reported females and males of *S. orcutti* reached maturity at 85 and 90 mm SVL, respectively, in southern California. In Baja California Sur, the smallest mature *S. orcutti* female (LACM 128083) measured 70 mm SVL and contained five enlarged ovarian follicles (> 8 mm diameter); the smallest mature male (LACM 128070) measured 68 mm SVL (spermiogenesis in progress, seminiferous tubules lined by clusters of sperm or metamorphosing spermatids). Both *S. orcutti* were collected in May which is within the height of reproductive activity for this species (Mayhew, *op. cit.*) and are from San José de Comondú (26.0625°N, 56.6900°W; datum WGS 84), which is north of the range of the congeners *S. hunsakeri* and *S. licki* (Grismer 2002. Amphibians and Reptiles of Baja California, Including its Pacific Islands and the Islands in the Sea of Cortés. University of California Press, Berkeley. 399 pp.).

I thank C. Thacker (LACM) for permission to examine *S. orcutti*.

STEPHEN R. GOLDBERG, Department of Biology, Whittier College, Whittier, California 90608, USA; e-mail: sgoldberg@whittier.edu.

***SPHAERODACTYLUS PACIFICUS* (Pacific Least Gecko). ENDOPARASITES.** *Sphaerodactylus pacificus* is endemic to Cocos Island (Isla de Cocos), Costa Rica (Savage 2002. The Amphibians and Reptiles of Costa Rica: A Herpetofauna Between Two Continents, Between Two Seas. University of Chicago Press, Chicago, Illinois. 934 pp.). There are, to our knowledge, no reports of helminths from *S. pacificus*. The purpose of this note is to establish the helminth lists for *S. pacificus* as part of ongoing studies of helminths in lizards from Central America.

Three *S. pacificus* (mean SVL = 40.0 ± 1.5 SD, range: 37–42 mm) deposited in the herpetology collection of the Natural History Museum of Los Angeles County (LACM), Los Angeles, California: (LACM 147972, 147976, 147977), collected April 1965, from Cocos Island (5.533°N, 87.067°W; WGS 84, elev. 610 m), Puntarenas Province, Costa Rica were examined for helminths.

The digestive tract was removed through a mid-ventral incision and the digestive contents from the esophagus, stomach, small and large intestines were examined under a dissecting scope. Nematodes found in the large intestine were cleared in a drop of glycerol, studied under a compound microscope and identified as *Parapharyngodon cubensis*; prevalence (number lizards infected/number lizards examined × 100) = 67%, intensity (number helminths per infected lizard) = 1.0. The *Parapharyngodon cubensis* was deposited in the United States National Parasite Collection (USNPC), Beltsville, Maryland, USA as (USNPC 103947).

Selected morphological characters of species within the genus *Parapharyngodon* were presented by Bursey and Goldberg (2005. J. Parasitol. 91:591–599) and we have assigned our specimens to *P. cubensis* based on those characters (i.e., spicule of 70 µm, 7 caudal papillae, smooth cloacal lip in the male, prebulbar ovary and stout tail spike in the female). *Parapharyngodon cubensis* has been found in a wide spectrum of reptiles throughout the West Indies (Dyer et al. 2001. Trans. Illinois State Acad. Sci. 94:161–165) and as a member of the Oxyuroidea, does not utilize an intermediate host (Anderson 2000. Nematode Parasites of Vertebrates. Their Development and Transmission. 2nd ed. CABI Publishing, Oxon, UK. 650 pp.). Transmission likely occurs by ingesting eggs from substrate while feeding. *Sphaerodactylus pacificus* represents a new host record. *Parapharyngodon cubensis* in Costa Rica is a new locality record.

We thank C. Thacker (LACM) for permission to examine *S. pacificus* which are part of the Costa Rica Expeditions Collection donated to LACM in 1998 by J. M. Savage.

STEPHEN R. GOLDBERG, Department of Biology, Whittier College, Whittier, California 90608, USA (e-mail: sgoldberg@whittier.edu); **CHARLES R. BURSEY**, Department of Biology, Pennsylvania State University, Shenango Campus, Sharon, Pennsylvania 16146, USA (e-mail: cxb13@psu.edu).

***TROPIDURUS ITAMBERE* (NCN). TONIC IMMOBILITY.** Tonic immobility, also known as "death feigning" or "thanatosis," is exhibited by a great variety of animals (Hoagland 1928. J. Gen. Physiol. 11:715–741). By simulating death, potential prey may inhibit the attack response of a potential predator. Locomotor escape, caudal autotomy, tail waving, and threat displays that may follow tonic immobility are considered secondary mechanisms of defense (Edmunds 1974. Defense in Animals. Longman Group, New York. 357 pp.). A widespread antipredator strategy, tonic immobility has been reported for virtually all vertebrate groups, including fishes (Wells et al. 2005. Mar. Freshwater Behav. Physiol. 38:71–78), snakes (Griffiths et al. 2007. J. Comp. Psychol. 121:123–129), birds (Hohtola 1981. Phys. Behav. 27:475–480) and mammals (Fraser 1960. Can. J. Comp. Vet. Sci. 24:330–334) In lizards, tonic immobility has been reported for species such as *Iguana iguana* (Prestrude and Crawford 1970. Anim. Behav. 18:391–395), *Anolis carolinensis* (Henning and Dunlap 1978. Behav. Ecol. 23:75–86), and *Carlia jarnoldae* (Langkilde et al. 2003. Herpetol. J. 13:141–148). Here, we provide for the first time a brief description of this behavior in *Tropidurus itambere*.

On 9 July 2010, we observed an adult male *T. itambere* (4.99 cm SVL) in a rocky field in the Cerrado bioregion, in the Reserva Biológica Unilavras – Boqueirão, municipality of Ingaí (21.34638°S, 44.99083°W, 1250 m elev.) in the state of Minas Gerais, Brazil. Upon capture, it exhibited tonic immobility for ca. 45 seconds. The behavior persisted after the animal was placed carefully on the ground. After ca. 1 min. the lizard righted itself and fled. During this observation of tonic immobility, the lizard kept its eyes closed and showed no external response to stimulation. The duration of this behavior varies among species and to a lesser degree for individuals within species (Hoagland 1928, *op. cit.*). Among Brazilian lizards, this behavior has been observed in the congeners *Tropidurus torquatus, T. hispidus, T. divaricatus, T. nanuzae* (Bertoluci et al. 2006. Herpetol. Rev. 37:472–473; Frost et al. 2001. Mol. Phylog. Evol. 21:352–371), as well as in *Liolaemus lutzae* (Rocha 1993. Cienc. Cult. 45:116–122), *Eurolophosaurus nanuzae* (Galdino and Pereira 2002. Herpetol. Rev. 33:54), and

E. divaricatus (Kohlsdorf et al. 2004. Herpetol. Rev. 35: 309–391), but has not been reported in *T. itambere* to our knowledge.

RAMON GOMES DE CARVALHO (e-mail: ramongomesbio@hotmail.com), **PRISCILA DA SILVA LUCAS** (e-mail: prilucass@gmail.com), and **IARA ALVES NOVELLI** (e-mail: iaranovelli27@gmail.com), Laboratório de Zoologia, Centro Universitário de Lavras, Rua Padre José Poggel, 506, Centenário, CEP 37200-000, Lavras, MG, Brazil.

SQUAMATA — SNAKES

***ACROCHORDUS GRANULATUS* (Marine File Snake). ABERRANT COLORATION.** *Acrochordus granulatus* is a coastal marine snake and one of three species in the family Acrochordidae. On 28 October 2009, while conducting research in collaboration with the Philippine National Museum, we observed a collection of twelve specimens in the pet trade that showed variation in color patterns and degree of pigmentation. The specimens were reported to have been collected from a single population in Quezon Province, Luzon Island, Philippines. Seven of the specimens possessed the normal color pattern observed for *A. granulatus* consisting of dark gray to black ground coloration with alternating lateral white bands that are discontinuous on the dorsal surface (Fig. 1C). Two specimens were observed to possess a leucistic color pattern, completely lacking pigmentation on the body, but still possessing dark eye pigmentation (Fig. 1A). The three remaining specimens possessed an intermediate color pattern of predominately white ground coloration and irregular dark gray to black dorsal blotches (Fig. 1B). This intermediate color pattern resulted in a "piebald" appearance, and was likely the result of partial leucism. To our knowledge, this is the first observation of full and partial leucism in *A. granulatus*.

FIG. 1. Two adult females and one adult male *Acrochordus granulatus* showing A) complete leucistic, B) partial ("piebald") leucistic, and C) normal color and pigmentation patterns.

Three specimens were donated to the Philippine National Museum, preserved, and deposited in the herpetological collections (CDS 5521 [female; total length = 550.6 mm; 48.0 g]: Fig. 1A; CDS 5539 [male; total length = 508.6 mm, 40.2 g]: Fig. 1B; CDS 5520 [female; total length = 536.7 mm; 40.0 g]: Fig. 1C).

CAMERON D. SILER, Department of Ecology and Evolutionary Biology, Natural History Museum and Biodiversity Institute, University of Kansas, Dyche Hall, 1345 Jayhawk Blvd, Lawrence, Kansas 66045-7561, USA (e-mail: camsiler@ku.edu); **EMERSON SY**, Herpetology Section, Zoology Division, Philippine National Museum, Rizal Park, Burgos St., Manila, Philippines (e-mail: emerson.sy@gmail.com).

***BITIS GABONICA* (Gaboon Viper). DIET AND PREY SIZE.** *Bitis gabonica*, a large terrestrial African viperid, is a strict sit-and-wait predator that frequently remains motionless for days or weeks at ambush sites (Warner 2009. Conservation Biology of the Gaboon Adder [*Bitis gabonica*] in South Africa. Unpubl. MSc thesis. Univ. Witwatersrand, South Africa. 121 pp.). During a radiotelemetry study of *B. gabonica* in northeastern South Africa, on 5 March 2007, a female (SVL = 899 mm; total length = 959 mm; mass = 1242 g) was observed in ambush posture next to a thicket in open woodland habitat (28.27598°S, 32.47460°E, datum: WGS84). On 13 March 2007, 83 m (linear distance) from the previous location, we found the snake with a very large meal in its stomach. Because the study was near its end and the prey record

FIG. 1. Female *Bitis gabonica* with antelope prey (*Cephalophus natalensis*).

COLOR REPRODUCTION SUPPORTED BY THE THOMAS BEAUVAIS FUND

was potentially valuable, the individual was carefully removed from the field and transported to the lab to induce regurgitation. Approximately 15 minutes after removal, the snake was discovered dead. Although *Bitis* in captivity have died after consuming meals close to their own body mass (Haagner 1988. Koedoe 31:246), we attribute the snake's death to stress from transport. A post-mortem (Fig. 1) revealed that the snake had consumed a *Cephalophus natalensis* (Red Duiker). The antelope had been bitten in the lower abdomen, and a single fang was found entangled in its fur. The *C. natalensis* was 104% of the snake's body mass, which is the highest relative prey mass (RPM) recorded for *B. gabonica* and also the first record of ungulate predation by the species in South Africa.

We thank the iSimangaliso Threatened Species Project for hosting the study, conducted with permission from Ezemvelo KwaZulu-Natal Wildlife (EKZNW SR/014) and the Animal Ethics Screening Committee of the University of the Witwatersrand (2006/31/04).

ALEXANDER**, School of Animal, Plant and Environmental Sciences, University of the Witwatersrand, Private Bag 3, Wits 2050, Guateng, South Africa (e-mail: graham@gecko.biol.wits.ac.za).

***BOA CONSTRICTOR* (Boa Constrictor). FORAGING BEHAVIOR.** *Boa constrictor* is often referred to as a sit-and-wait or ambush forager that chooses locations to maximize the likelihood of prey encounters (Greene 1983. *In* Janzen [ed.], Costa Rica Natural History, pp. 380–382. Univ. Chicago Press, Illinois). However, as more is learned about the natural history of snakes in general, the dichotomy between active versus ambush foraging is becoming blurred. Herein, we describe an instance of diurnal active foraging by a *B. constrictor,* illustrating that this species exhibits a range of foraging behaviors.

At 1120 h on 25 May 2007, on Cayo Cochino Grande, Cayos Cachinos, Honduras (15.9711928037812°N, 86.4739467195224°W, NAD 83/WGS 84), we saw several *Artibeus jamaicensis* (Jamaican Fruit Bat) fly from a living Cohune Oil Palm (*Attalea cohune,* Arecaceae) approximately 8 m above the ground. We noticed that the bats were disturbed from their daytime roost (likely beneath a frond of the *A. cohune*) by a *B. constrictor* (male; SVL = 760 mm; total length = 118 mm; 268 g including prey). The snake fell to the ground while simultaneously constricting four bats and continued to constrict and kill all four bats on the ground. Over approximately 1.5 h we observed the snake consume two of the four individuals (one adult male and one adult female) headfirst and then take refuge under nearby palm fronds on the forest floor. The two bats that were abandoned by the snake were a female (42 g) and a male (29 g). After measuring, we released the *B. constrictor* at the point of capture without palpating the two bats it had consumed.

Boa constrictor is known to prey upon at least four species of bats (including *A. jamaicensis*; Esbérard and Vrcibradic 2007. Rev. Brasil. Zool. 24:848–853). Previous observations of bat predation by *B. constrictor* describe snakes entering caves or tree cavities to capture roosting bats during the day (Arendt and Anthony 1986. Carib. J. Sci. 22:219–220; Thomas 1974. J. Herpetol. 8:188). Bats roosting in caves and tree cavities would be a predictable prey source for *B. constrictor*. In contrast, although female *A. jamaicensis* nested in tree hollows and moved day roosts infrequently on Barro Colorado Island, males roosted in foliage and changed day roost sites frequently (every 3–13 days; Morrison 1978. Ecology 59:716–723). We observed this mixed-sex group of *A. jamaicensis* roosting in foliage suggesting a relatively ephemeral roost site. Thus our observations suggest that *B. constrictor* uses active, sometimes diurnal foraging to locate prey such as roosting bats. Additionally, this observation is the first to document a *B. constrictor* apprehending and constricting multiple bats simultaneously.

***BOIGA DENDROPHILA* (Mangrove Cat Snake). DIET.** *Boiga dendrophila* is a large (to 250 cm total length) colubrid snake, known from both primary and disturbed lowland forests and mangrove swamps of Southeast Asia (Das 2006. A Photographic Guide to the Snakes and Other Reptiles of Borneo. New Holland Publishers, Ltd., London. 144 pp.; David and Vogel 1996. The Snakes of Sumatra: An Annotated Checklist and Key with Natural History Notes. Edition Chimaira, Frankfurt am Main. 260 pp.). Its diet is known to include vertebrates such as frogs, lizards, birds, and rodents; one snake species (*Ahaetulla prasina*) has also been documented (Stuebing and Inger 1999. A Field Guide to the Snakes of Borneo, Natural History Publications, Sdn. Bhd. Kota Kinabalu. 235 pp.).

At 2000 h on 13 September 2009, an adult *B. dendrophila* (total length ca. 1 m) was encountered in tree branches on the bank of Sungei Bawang (01.0613°N, 110.1976°E, datum WGS84), a perennial stream flowing over granite-sandstone substrate at Kubah National Park at the Matang Range, Sarawak, East

FIG. 1. *Boiga dendrophila* consuming a *Parias sumatranus* in Kubah National Park, East Malaysia.

COLOR REPRODUCTION SUPPORTED BY THE THOMAS BEAUVAIS FUND

Malaysia (western Borneo). This individual was observed to attack, subdue, and swallow a juvenile (total length < 1 m) *Parias sumatranus,* a large (to 1.6 m) and dangerously venomous viper. The prey was approached while it was resting on a horizontal branch of a tree overhanging the stream, ca. 3 m from ground. It was then seized by the head, rapidly followed by the tail, which arched forward to grab the neck region of the prey, which was then swallowed in ca. 30 min (Fig. 1). This observation represents the first reports of foraging behavior in *B. dendrophila*, as well as the first record of a venomous snake in its diet.

We thank the Institute of Biodiversity and Environmental Conservation, Universiti Malaysia Sarawak, for support of our studies, and the Sarawak Forest Department for permission.

PUI YONG MIN (e-mail: pui8783ibec@gmail.com), and **INDRANEIL DAS** (e-mail: idas@ibec.unimas.my), Institute of Biodiversity and Environmental Conservation, Universiti Malaysia Sarawak, 94300 Kota Samarahan.

***BOIGA IRREGULARIS* (Brown Treesnake). PREDATION AND DIET.** Introduced *Boiga irregularis* on the Western Pacific island of Guam feed on a wide variety of vertebrate prey. Stomach contents of juvenile *B. irregularis* specimens include a large proportion of lizards, especially geckos and skinks (Savidge 1988. J. Herpetol. 22:275–282). Guam is also home to *Varanus indicus* (Mangrove Monitor), which reach an adult size of ca. 560 mm SVL (Wikramanayake and Dryden 1988. Herpetologica 44:338–344). *Varanus indicus* are opportunists that feed primarily on arthropods (Dryden 1965. Micronesica 2:72–76), but they may prey on *B. irregularis* (Fritts and Rodda 1998. Annu. Rev. Ecol. Sys. 29:113–140; McCoid and Witteman 1993. Herpetol. Rev. 24:105). Occasionally the roles are reversed and the snakes prey on monitor eggs (Savidge 1988, *op. cit.*), but in general, interactions between *V. indicus* and *B. irregularis* remain poorly documented.

While working at our main study site in northwestern Guam in the late morning of 12 May 2010, the first two authors observed a large (ca. 500 mm SVL) adult *V. indicus* perched ca. 4 m above ground in a large Fagot Tree (*Neisosperma oppositifolia*). On the ground was a fresh bolus containing the regurgitated remains of a large *B. irregularis*. We scanned the bolus for a PIT tag since virtually all adult snakes in our study population have been previously tagged. The bolus contained the PIT tag from a large male snake that had been captured 22 days previous to this observation. On that date of capture, it measured 1305 mm SVL, 1645 mm total length, and weighed 307 g. At that time, it was in good health and had an above-average condition index of 1.35 (1.00 is the long-term average for snakes across Guam), so we have no reason to suspect the monitor had scavenged a snake that was already dead. Assuming the monitor measured 500 mm SVL, its weight should have been ca. 2 kg (Wikramanayake and Dryden 1988, *op. cit.*). Hence, the snake's mass was approximately 15% of the monitor's mass.

We found evidence for predator-prey role reversal while searching for snakes in the same part of Guam on the evening of 17 May 2010. The third author captured a male *B. irregularis* that was 865 mm SVL and had a gross weight of 71 g, which included an obvious food bulge in its stomach. As part of a study on stomach contents and reproductive characteristics, it was brought to the lab for euthanasia and necropsy the following day. The prey item was found to be a juvenile *V. indicus* (head and neck partially digested, weight of remains 7.8 g, tail length 134 mm).

Predation on *B. irregularis* by *V. indicus* may be uncommon, as the former normally seeks diurnal shelter in arboreal vine tangles, tree hollows, or even underground refugia (unpubl. data); all of which may be difficult for an adult monitor to access. However, the snakes can probably access virtually any nocturnal refugium used by a juvenile monitor, and we suspect that predation pressure may affect recruitment of monitors.

***BOTHRIECHIS SCHLEGELII* (Eyelash Palm-Pitviper). DIET.** *Bothriechis schlegelii* has been recorded feeding on a variety of small vertebrates including frogs, lizards, birds, and small mammals (Campbell and Lamar 2004. The Venomous Reptiles of the Western Hemisphere. Comstock Publishing Associates, Ithaca, New York. 898 pp.). Given the nocturnal and arboreal habits of *B. schlegelii* it is not surprising that bats have been documented in their diet, yet records of chiropterophagy in this species are limited to only two accounts. In one case, a *B. schlegelii*, found in a shipment of bananas that was believed to have originated in Honduras, regurgitated the nectar-feeding bat, *Glossophaga soricina* (Groves 1961. Herpetologica 17:277). The other, a case from Costa Rica, involved a *B. schlegelii* that contained an unidentified bat in its stomach (Hardy 1994. Sonoran Herpetol. 7:108–113). Here we report the fist record of *B. schlegelii* consuming a *Myotis riparius*.

On 16 August 2008 at 1920 h, a subadult *B. schlegelii* (UF 155962; SVL = 40.6 cm; tail length = 6.8 cm) was found in the process of consuming a *M. riparius* (UF 31760; SVL = 3.6 cm). The incident was recorded by SLT and Juan Francisco López while walking a nocturnal transect, Pamka Buhna, in the Kipla Sait Tasbaika indigenous territory of Reserva de la Biósfera Bosawas, Departamento Atlántico Norte, Nicaragua (14.3653°N, 84.9349°W, datum: WGS84; elev. 186 m). The snake was encountered ca. 3 m above ground holding onto an epiphyte on the truck of a large tree, and was in the latter stages of consuming the bat. It took ca. 5 min for the snake to finish consuming the bat, after which, the snake was collected and later preserved. Both specimens were deposited in the Florida Museum of Natural History.

Approximately 20 species of snakes have been documented feeding on bats in the Neotropics, the majority being boiids and colubrids, with only four representatives of Viperidae (Esbérard and Vrcibradic 2007. Rev. Bras. Zool. 24:848–853). Esbérard and Vrcibradic (*op. cit.*) conclude that most documented cases of bat predation by snakes in the Neotropics are within or around the entrance of bat refuges, indicating the possibility that snakes are drawn to these areas due to the abundant concentration of prey. Hardy (*op. cit.*) stated that the *B. schlegelii* found with a bat in its stomach was encountered sitting near the opening of a tree trunk that led to a bat roost, which may suggest that this feeding strategy is also employed by this species. Although we did not witness the snake capture the bat in the predation event documented here, there was no evidence of a bat roost in the vicinity. Therefore, we suspect this event was an opportunistic prey capture.

We thank the St. Louis Zoo (SLZ UFF-8165-Nickerson) and the Reptile and Amphibian Conservation Corps (RACC 07-08 C) for financial support. Research and collecting permits were obtained under the authority of MARENA permit No. 006–008.

***BOTHROPOIDES* (= *BOTHROPS*) *JARARACA* (Jararaca). DIET.** Predation on anurans by juvenile *Bothropoides jararaca* has frequently been reported (e.g., Sazima 1991. Copeia 1991:245–248; Sazima 1992. *In* J. Campbell and E. Brodie, Jr. [eds.], Biology of Pitvipers, pp. 199–216. Univ. Texas Press, Arlington; Sazima and Haddad 1992. *In* Morellato [ed.], História Natural da Serra do Japi, pp. 212–237. UNICAMP, Campinas; Hartmann et al. 2003. Phyllomedusa 2:35–41). Although records of lizards as prey are scarce, Sazima (1992, *op. cit.*), reported *Hemidactylus mabouia* as a prey item of two juvenile snakes and Sazima (1991, *op. cit.*) and Sazima and Haddad (1992, *op. cit.*) noted that lizards must be included in the diet of the species.

On 23 March 2003, during an expedition to the southern portion of the Atlantic Forest of Paraná State, Brazil, I collected a juvenile *B. jararaca* (SVL = 248 mm; 8.6 g) actively crawling along a forest edge at 1630 h. Examination of the specimen revealed the remains of an adult gymnophthalmid lizard, *Placosoma glabellum*, in the snake's stomach. The lizard had been swallowed head first and was partially digested, but comparisions with other specimens from the herpetological collection of Museu de História Natural Capão da Imbuia at Curitiba (MHNCI) suggested that it was larger than 40 mm SVL. Juvenile *B. jararaca* exhibit criptic coloration and are known to use caudal luring behavior to lure amphibians, but it is possible that they may also lure lizards and other arthropod predators, such as birds (Sazima 1991, *op. cit.*). This is the first record of an interaction between *B. jararaca* and a gymnophthalmid lizard, and confirms the suspicions that juvenile *B. jararaca* consume lizards. The snake and lizard were deposited at the herpetological collection of MHNCI (MHNCI 11117).

SERGIO AUGUSTO ABRAHÃO MORATO, Universidade Tuiuti do Paraná, Faculdade de Ciências Exatas e de Tecnologia – UTP/FACET. R. Sidney A. Euzébio da Motta, 450. 80.530-260, Curitiba, Paraná, Brazil; e-mail: sergio.morato@utp.br; sergio@stcp.com.br.

***BOTHROPS* (= *RHINOCEROPHIS*) *ALTERNATUS* (Urutu Pitviper). MICROHABITAT.** *Bothrops alternatus* is a widespread species that occurs primarily in humid habitats across Brazil, Paraguay, Uruguay, and Argentina (Campbell and Lamar 1989. The Venomous Reptiles of Latin America, Cornell Univ. Press, Ithaca, New York. 425 pp.). Although it is usually indicated to occur near wetlands, no precise information has been presented on specific microhabitats occupied in these particular situations. While conducting research at the Iberá wetlands, Corrientes province, Argentina, on 7 May 2000, we collected a specimen of *B. alternatus* 10 km inside the swamp, occupying a floating substrate locally known as "embalsado" (Fig. 1; Laguna Luna, 28.13778°S, 56.82222°W, datum: WGS 84). The "embalsado" is essentially a vegetated Histosol (organic soil type), of up to 2 m depth, consisting primarily of dead plant material that, depending on the water level, floats or rests on the bottom. At Iberá, these soils support sophisticated plant communities, mainly grasslands, but that in some locations can even include shrubs and trees. The *B. alternatus* was found basking at the base of a mat, in a small open spot (ca. 20 m wide) near the edge of a lagoon, in an area otherwise dominated by the tall and dense grass, *Rhynchospora corymbosa* (Ciperaceae). The open spot resembled a peat, characterized by the presence of puddles, open soil (mainly vegetation debris) and *Sphagnum* (Sphagnaceae) patches. The area was scattered with feces of *Cavia aperea* (Rodentia: Cavidae). The snake was a 109.5 cm SVL, severely emaciated, adult female. Dissection revealed that it had given birth recently, exhibiting a total of 18 elliptic oviducal scars. The specimen was deposited at the collection of the Museo Argentino de Ciencias Naturales "Bernardino Rivadavia" (MACN 39628).

FIG. 1. *Bothrops alternatus* basking at the base of a mat of grass, upon a carpet of peat-mosses (*Sphagnum*), Iberá wetland, Argentina.

COLOR REPRODUCTION SUPPORTED BY THE THOMAS BEAUVAIS FUND

Although *B. alternatus* has been found in the vicinity of several types of wetlands in the Iberá area (Alvarez et al. 2003. *In* Alvarez [ed.], Fauna del Iberá, pp. 99–178. Editorial Universitaria de la Univ. Nacional del Nordeste, Corrientes, Argentina), it was not known to occur inside the swamp in the microhabitat described here. The significant distance from the shore and the evidence of reproduction suggests that some floating habitats at the Iberá wetland can harbor populations of this species, presumably sustained by locally dense rodent populations.

I acknowledge the Universidad del Salvador (Argentina) and the Universita di Siena (Italy) for supporting my research in Corrientes province, Argentina.

TOMAS WALLER, La Pampa 1815, 5th Floor "B", 1428 Buenos Aires, Argentina; e-mail: twaller@fibertel.com.ar.

***BOTHROPS MOOJENI* (Brazilian Lancehead). DIET.** *Bothrops moojeni* is a large pitviper that inhabits riparian areas in central and southeastern Brazil throughout the Cerrado physiogeographic region (Borges and Araújo 1998. Rev. Bras. Biol. 58:591–601). The diet of *B. moojeni* consists of centipedes, frogs, lizards, snakes, birds, and mammals (Nogueira et al. 2003. J. Herpetol. 37:653–659). Here we report predation on an adult treefrog, *Scinax fuscovarius*, by a juvenile *B. moojeni*.

At 1100 h on 10 Jan 2008, at the edge of the Sucuriú River, Três Lagoas municipality, State of Mato Grosso do Sul, Brazil, a

juvenile *B. moojeni* was observed grasping an adult *S. fuscovarius* by the rear legs. When disturbed by our presence, the snake retreated into vegetation.

***CEMOPHORA COCCINEA COPEI* (Northern Scarletsnake). DIET.** *Cemophora coccinea* is a small fossorial snake thought to feed largely on the eggs of other reptiles (Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Institution Press, Washington D.C. 680 pp.). On 17 August 2007, while surveying a study site in Chesterfield Co., South Carolina, USA, I captured a female *C. coccinea* (349.25 mm total length; 8 g) crossing the road at night. Shortly after, I found a juvenile *Pantherophis guttatus* (total length = 279.4 mm; 5 g) that had recently been hit by a vehicle. Due to a lack of collection bags, I placed the dead *P. guttatus* in the same bag as the *C. coccinea*. Approximately 45 min later, I opened the bag and only found the *C. coccinea*; the *Cemophora* had eaten the *P. guttatus*. To our knowledge *P. guttatus* has not been documented in the diet of *C. coccinea* (Ernst and Ernst, *op. cit.*). Though ophiophagy has been reported in *C. coccinea* (Conant and Collins 1998. A Field Guide to Reptiles and Amphibians of Eastern and Central North America. Houghton Mifflin Co., New York. 616 pp.), it is very uncommon and has not been documented in any accounts from North or South Carolina (Palmer and Braswell 1995. Reptiles of North Carolina. Univ. North Carolina Press, Chapel Hill. 412 pp.; S. Bennett, pers. comm.). The prey item comprised 62.5% of the *C. coccinea*'s body weight.

***CHIRONIUS EXOLETUS* (Vine Snake). REPRODUCTIVE BEHAVIOR.** Few data are available on the mating behavior of neotropical snakes in the wild (Greene 1997. Snakes: the Evolution of Mystery in Nature. University of California Press, Los Angeles. 351 pp.). In the Brazilian state of Rondônia, newborn *Chironius exoletus* have been found in November and February, and females with eggs and enlarged follicles have been observed from November through March (Bernarde and Abe 2006. S. Amer. J. Herpetol. 1:102–113).

On 6 September 2009 at 1730 h, in forest along the São Miguel River, Municipality of Seringueiras, Rondônia state, Brazil (12.0039722°S, 63.0351389°W; datum WGS84; elev. ca. 160 m), we observed a pair of *C. exoletus* on the ground engaged in courtship and mating (tactile-alignment, intromission, and coitus; Gillingham 1986. *In* Seigel et al. [eds.], Snakes: Ecology and Evolutionary Biology, pp. 184–209. McGraw Hill, New York). The duration of copulation was 27 min. Another unsexed adult *C. exoletus* was observed approximately 1 m away, resting about vegetation. The snakes were not captured.

***COLUBER CONSTRICTOR* (North American Racer). CANNIBALISM AND DEFENSIVE BEHAVIOR.** Cannibalism by racers has been described in both field and laboratory conditions (Mitchell 1986. SSAR Herpetol. Circ. 15:1–37). Most reports are from stomach contents and lack behavioral observations. Cannibalism might occur as a byproduct of captive feeding, from a competitive interaction, or as direct consumptive behavior; therefore information describing these interactions is valuable. This observation is also the first documentation of an anchoring behavior used by *C. constrictor* as an attempt to avoid predation.

On 6 June 2008 at approximately 1030 h, I documented cannibalism between male *C. constrictor* at the Department of Energy's Savannah River Site, Aiken Co., South Carolina, USA. While driving on a gravel road, I observed a *C. constrictor* (SVL = 107 cm, total length = 143 cm) enter perpendicular to the road from the grassy edge in front of me. As I quickly halted the vehicle, the racer increased speed away from me parallel to the road's edge. The snake moved approximately 6 m and came to an abrupt stop at the road's edge where it attacked another smaller *C. constrictor* (SVL = 70 cm, total length = 98 cm). Following the attack and a short struggle, the larger snake and aggressor (hereafter Snake A) raised above the grass with the smaller snake (hereafter Snake B) in its grasp (~3 cm posterior to head). With raised anterior portions of body and Snake B in mouth, Snake A moved

perpendicular and away from the road (~6 m away) into dense brush. Occasionally the snakes' bodies were entwined, biting one another. There were long periods of what appeared to be rest with slow biting movements followed by the occasional quick and aggressive struggles that lasted only seconds at a time. In defending itself, Snake B bit and coiled around Snake A and at one point it anchored to surrounding vegetation by biting itself. The anchoring was performed by extending the anterior region of its body over a vine and then biting itself. Snake B was thus secured to the vine and Snake A had difficulty pulling it free (with a "tugging" motion). While anchoring, Snake B worked its way down its own body and bit the bottom jaw of Snake A allowing brief freedom from the grasp of Snake A. After a nearly 60 min struggle, Snake A was able to overcome Snake B and consumed it within 10 min. During consumption, Snake A vigorously vibrated its tail, possibly in response to my presence. After consumption, I captured Snake A whereupon it regurgitated Snake B, which was still alive. Snake A was starting to shed within one day following capture and Snake B was close to shedding having nearly opaque eyes at the time of capture.

I thank Julian Resasco for use of camera, Kimberly Andrews for advice and comments, and J. D. Willson for helpful comments that improved this note.

CALEB R. HICKMAN, Savannah River Ecology Laboratory, Drawer E, Aiken, South Carolina 29802, USA; present address: Washington University, Department of Biology, 1 Brookings Drive, St. Louis, Missouri 63130, USA; e-mail: calebhickman@gmail.com.

COLUBER CONSTRICTOR **(North American Racer). PREY SIZE.** *Coluber constrictor* is a large (to 191.1 cm total length) colubrid snake native to a variety of open habitats in North America (Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Institution Press, Washington, DC. 668 pp.). It is a nonvenomous, nonconstricting dietary generalist that is known to consume a wide range of vertebrate and invertebrate prey items, including other snakes. Here we report a juvenile *C. constrictor* feeding on a relatively very large ophidian prey item, to our knowledge the largest relative prey mass reported for this species.

At 1300 h on 20 April 2010, a juvenile *C. constrictor* (female, SVL = 289 mm, 12.58 g) was found by a terrier among dry leaves in a grassy roadside at Rocky Branch Nature Preserve, Clark Co., Illinois, USA (39.46282°N, 87.77423°W, datum WGS 84). We noticed that the snake's body had a lumpy, kinked quality, and so returned it to the laboratory where it regurgitated an adult male *Diadophis punctatus* (Ring-necked Snake) measuring 265 mm SVL with a mass of 4.38 g, which had been swallowed headfirst. The mass of the racer without the prey item was 8.20 g, so the prey represented 53.4% of the predator's body mass and measured 91.7% of the body length.

Coluber constrictor is known to feed on other snakes, including *D. punctatus*, but generally consumes relatively small prey. Halstead et al. (2008. Copeia 2008:897–908) found a significant positive relationship between snake mass and prey mass for *C. constrictor* in Florida, with a mean relative prey mass of 6.8 ± 1.4%, although racers in their study had consumed no other snakes. Fitch (1982. *In* N. J. Scott, Jr. [ed.], Herpetological Communities: A Symposium of the SSAR and HL, August 1977. USFWS, Wildl. Res. Rep. 13. 239 pp.) found *D. punctatus* to be the fifth most common vertebrate prey item consumed by racers in Kansas and estimated that *C. constrictor* consumed on average 23 g/ha of *D. punctatus* annually, compared to >1500 g/ha of small mammals and almost 300 g/ha of insects. About 12% of racer stomach contents from Illinois contained reptiles, with a larger proportion containing insects (48%) and mammals (43.5%; Klimstra 1959. Copeia 1959:210–214).

ANDREW M. DURSO (e-mail: amdurso@gmail.com) and **NICHOLAS M. KIRIAZIS** (e-mail: nmkiriazis@eiu.edu), Department of Biological Sciences, Eastern Illinois University, Charleston, Illinois 61920, USA.

COLUBER CONSTRICTOR MORMON **(Western Yellow-bellied Racer) and** ***PITUOPHIS CATENIFER DESERTICOLA*** **(Great Basin Gopher Snake). DIET.** Although some aspects of *Coluber constrictor mormon* and *Pituophis catenifer deserticola* ecology

TABLE 1. Diet items collected from *Coluber constrictor mormon* and *Pituophis catenifer deserticola* from Antelope Island State Park, Utah, USA, in 2005. (U) denotes an individual of unknown sex and (*) indicates a gravid female.

have been studied within the Great Basin (Brown 1973. Ph.D. Diss., Univ. Utah, Salt Lake City; Parker and Brown 1980. Milwaukee Public Mus. Publ. Biol. Geol. 7:1–104), few studies have examined their feeding habits and there are no published records from any islands within the Great Salt Lake. This lack of basic natural history information is a major impediment to the conservation of these species, particularly in light of degradation of local island landscapes by exotic and invasive species. While conducting research to examine the effects of Cheatgrass (*Bromus tectorum*) on snake populations at Antelope Island (Hall et al. 2009. West. N. Am. Nat. 69:88–95) we gathered information on the diets of *C. c. mormon* and *P. c. deserticola*.

Data were collected from June through September 2005 at Antelope Island State Park in Davis Co., Utah, USA. Antelope Island is the largest of the ten islands found within the Great Salt Lake and covers over 113 km^2. Live snakes were captured using hardware cloth drift fences with funnel traps or by hand and freshly killed snakes were recovered from the island's roads. Live snakes were palpated to regurgitate recently ingested prey items and all dead snakes were dissected and their stomach contents were examined.

Diet information was obtained from 12 *C. c. mormon* and two *P. c. deserticola* (Table 1). Despite the large geographic ranges of *C. c. mormon* and *P. c. deserticola* we found that stomach contents were similar to those previously reported for these species (Fitch 1963. Univ. of Kansas Publ. Mus. Nat. Hist. 15:351–468; Rodriguez-Robles 2002. Biol. J. Linn. Soc. 77:165–183). The majority of prey items recovered from *C. c. mormon* were invertebrates, representing 65% of the total diet, whereas rodents represented 29% and a lizard was recovered from a single female. Although similar diet items have been recorded for *C. c. mormon*, the proportion of snakes with rodents was much higher than previously reported for the region (Brown 1973, *op. cit.*). This may be a consequence of the different methods used to acquire samples; diet of road-killed snakes included a larger proportion of invertebrates than diet of trapped snakes. Our data support previous findings that *C. c. mormon* prefer orthopterans among invertebrate prey and that larger females incorporate vertebrates into their diet (Shewchuk and Austin 2001. Herpetol. J. 11:151–155). The two *P. c. deserticola* examined both contained *Microtus* sp., as has been reported for this species in the Great Basin (Rodriguez-Robles, *op. cit.*).

We thank E. Hall and N. Pietsch for field assistance and dietary item examination. We also thank the Antelope Island State Park personnel, S. Bates, G. Mortensen, and J. Hatch for their support.

LUCAS K. HALL (e-mail: lucashall4@gmail.com), Wildlife and Wildlands Conservation, Department of Plant and Wildlife Sciences, 275 WIDB, Brigham Young University, Provo, Utah 84602, USA; **JOHN F. CAVITT** (e-mail: jcavitt@weber.edu), Department of Zoology, Weber State University, 3848 Harrison Boulevard, Ogden, Utah 84408-2505, USA.

***COLUBER* (= *MASTICOPHIS*) *FLAGELLUM* (Coachwhip). UNUSUAL FEEDING BEHAVIOR.** Two of us (DK and DK) observed and photographed an unusual feeding event of an adult *Coluber flagellum piceus* (Red Racer), 5 km W of Wickenburg, Arizona, USA at 1145 h, 28 April 2007, elev. 670 m, air temperature 27–32°C. The snake, which seemed undisturbed by observers, started biting a dead branch of a tree. It then moved a few cm away from the branch for about 10 sec, returned and broke off a 2.5 × 1.3 cm piece of the branch and swallowed it (Fig. 1).

PHOTO BY DEBBIE KEISER

FIG. 1. *Coluber flagellum piceus* consuming small portion of stick after breaking it off the branch.

The piece of the stick eaten looks like a scaly lizard. Fenner et al. (2008. Herpetofauna 38:105–109) showed that *Pseudonaja textilis* (Australian Eastern Brown Snake) are attracted to motionless unscented models of *Tiliqua adelaidensis* (Pigmy Bluetounge Lizards), as well as live lizards, and suggested that the shape of the lizard is sufficient to elicit an attack. The stick in these observations of *C. flagellum* likely looked enough like a lizard for a snake to eat it. Alternately, it is possible that residual scent on the branch from a potential prey item could have elicited attack by the snake.

DALE KEISER, DEBRA KEISER, 35600 South Antelope Creek Rd., Wickenburg, Arizona 85390, USA; **BAYARD H. BRATTSTROM**, Horned Lizard Ranch, P.O. Box 166, Wikieup, Arizona 85360, USA (e-mail: bayard@hughes.net).

***COLUBER* (= *MASTICOPHIS*) *LATERALIS EURYXANTHUS* (Alameda Striped Racer) and *LAMPROPELTIS GETULA CALIFORNIAE* (California Kingsnake). PREDATION AND MAXIMUM PREY LENGTH RATIO.** While most recent research on the federally threatened *Coluber lateralis euryxanthus* has focused on habitat use and demography, other ecological aspects such as causes of mortality in this subspecies remain poorly understood. Natural predation on the related *C. l. lateralis* was recorded by Fitch (1949. Am. Midl. Nat. 41:513–579) and included 50 occurrences by Red-tailed Hawks (*Buteo jamaicensis*), seven by Great Horned Owls (*Bubo virginianus*), and seven by Coyotes (*Canis latrans*). In addition, Jennings (1997. Herpetol. Rev. 28:205–206) observed a *C. l. lateralis* being carried away in the talons of an American Kestrel (*Falco sparverius*). All of these documented predators are found in the same habitats as *C. l. euryxanthus* and likely prey upon this threatened taxon as well. Herein, we describe two separate instances of predation on *C. l. euryxanthus* by a well-known ophiophage, *Lampropeltis getula californiae*, and discuss associated predator-prey length ratios.

On 26 May 2009, at 1230 h, M. Yacelga discovered an adult female *L. g. californiae* (SVL = 950 mm; total length = 1018 mm)

PHOTO BY M. YACELGA

FIG. 1. An adult *Lampropeltis getula californiae* consuming a *Coluber lateralis euryxanthus* from Contra Costa Co., California, USA.

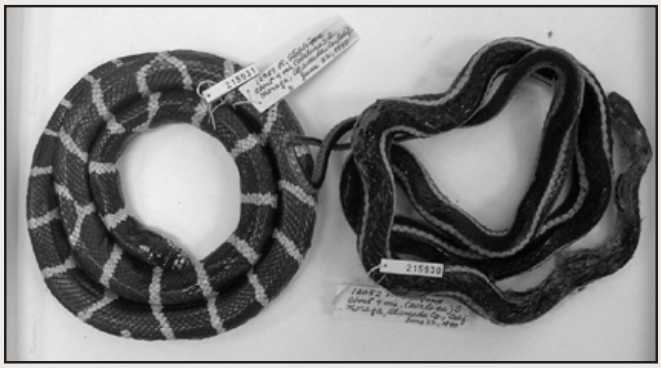

PHOTO BY K.D. WISEMAN

FIG. 2. An adult *Lampropeltis getula californiae* (MVZ 215931, left) that consumed a *Coluber lateralis euryxanthus* (MVZ 215930) from Alameda Co., California, USA.

in a drift fence funnel trap at the edge of coastal scrub/chaparral and grassland habitats approximately 2.3 km NW of Briones Reservoir, Contra Costa Co,, California, USA (37.950135°N, 122.217778°W, datum: WGS 84). When initially discovered, the kingsnake had already swallowed the anterior third of the body of an adult male *C. l. euryxanthus* (SVL = 832 mm; total length = 1157 mm; 134 g; Fig. 1). The racer had been initially captured and pit-tagged in September 2005 and was last recaptured on 8 May 2009. The kingsnake was removed from the trap for photographic documentation and left undisturbed while it continued to consume the racer. After approximately 30 min, the kingsnake had disappeared and the racer was not observed in the vicinity and had presumably been consumed by the kingsnake.

On 22 June 1990, an adult *L. g. californiae* (MVZ 215931; SVL = 839 mm; total length = 962 mm; 180 g [live]) was collected 1.1 km W of the corner of Brown Ranch Road on Old Airstrip Road (37.79259°N, 122.10416°W, datum: WGS 84), approximately 6.4 km S of Moraga, Alameda Co,, California, USA. The kingsnake had recently consumed an adult female *C. l. euryxanthus* (MVZ 215930; SVL = 838 mm, total length = 1150 mm; 129.2 g [preserved]) head-first (R.C. Stebbins, unpubl. field notes; Fig. 2).

Although the first instance of predation is complicated by the fact that the racer was confined within a funnel trap and could not have escaped the predator (or may have even attracted it), our second observation clearly demonstrates that *L. g. californiae* preys upon *C. l. euryxanthus* under natural conditions. Whipsnakes and racers (including *C. constrictor*, *C. lateralis*, *C. flagellum*, and *C. taeniatus*) are relatively common prey of *L. g. californiae* and account for approximately 5% of their overall diet, and 17% of the snake diversity consumed based upon the examination of 2,660 museum specimens, published literature, unpublished field notes, and personal communications (K. D. Wiseman, H. W. Greene, D. J. Long, and M. S. Koo, unpubl. data).

Jackson et al. (2004. Zoology 107:191–200) demonstrated that under captive conditions, *L. g. californiae* were capable of ingesting *Pantherophis guttatus* (Red Cornsnakes) with total lengths much greater than their own SVL. They accomplished this feat through several mechanisms: 1) anterior stretching of the stomach and esophagus, 2) bending the prey snake into longitudinal waves, and 3) folding of the tail tip (Fig. 2). A maximum length ratio (LR = prey total length/predator SVL) of 1.29 was accomplished by one kingsnake which completely digested its prey (Jackson et al., *op. cit.*). Three other kingsnakes completely ingested snakes with LR values of 1.07 to 1.21, however each regurgitated them after 4–7 days. Another kingsnake attempted to ingest a snake with an LR of 1.39, but regurgitated it before ingestion was complete. The kingsnake reported in our first observation (Fig. 1) had a LR of 1.22 and the second (MVZ 215931) had an LR of 1.37 (Fig. 2).

We thank Karen E. Swaim, Robert C. Stebbins, John C. Garcia, Joseph E. Drennan, Harry W. Greene, Jimmy A. McGuire, Carol L. Spencer, and Gary A. Beeman for various contributions in preparing this note. Trapping was conducted under USFWS permit # TE-815537.

***CROTALUS MITCHELLII* (Speckled Rattlesnake) and *CROTALUS RUBER* (Red Diamond Rattlesnake). ECTOPARASITES.** *Crotalus mitchellii* and *C. ruber* occur in a wide variety of predominantly dry habitats in the southwestern United States and México (Campbell and Lamar 2004. The Venomous Reptiles of the Western Hemisphere. Cornell Univ. Press, Ithaca, New York. 898 pp.). *Crotalus* spp. are known to be parasitized by several tick species including *Amblyomma dissimile*, and *Dermacentor* spp. (Klauber 1997. Rattlesnakes: Their Habits, Life Histories, and Influence on Mankind. Univ. California Press, Berkeley. 1533 pp.; Campbell and Lamar, *op. cit.*). Here we report novel tick-host relationships involving two species of rattlesnakes.

Rattlesnakes were captured at night, examined for ectoparasites and released at the site of capture. All visible ectoparasites were removed using forceps, preserved, and identified under a compound light microscope in the laboratory. On 6 November 2004, at 2150 h, an adult female *C. mitchellii* (total length [TL] ca. 700 mm) was collected along the road from La Paz to San Juan de la Costa, Baja California Sur, México (24.194733°N, 110.556789°W, WGS84). The female snake had two tick larvae (ZMB 48383, one larva was destroyed during identification), both swollen with blood meals, between the scales on the body. On 10 November 2004, at 2120 h, an adult female *C. ruber* (TL

ca. 800 mm) was found on the road from Insurgentes to Puerto López Mateos, Baja California Sur, México (25.761458°N, 112.010964°W, WGS84). The snake had five larvae and nymph ticks (ZMB 48380), all filled with host blood, between the scales on the body. A juvenile *C. ruber* (TL ca. 300 mm) was collected on 25 November at around 2100 h on the highway Mex 1, Baja California Norte, México (29.983342°N, 115.206078°W, WGS84). The juvenile had six larvae and nymph ticks (ZMB 48381), filled with blood, on the body sides. On 28 November 2004 at 2020 h, an adult male *C. ruber* (TL ca. 700 mm) was found on the highway Mex 12 from Bahía de los Ángeles to the highway Mex 1, Baja California Norte, México (29.052358°N, 114.121942°W, WGS84). The snake had 10 larvae and nymph ticks (ZMB 48382), one was on the neck, and the others were on the snake's back and body side engorged with blood.

All ticks were identified as the soft tick *Ornithodoros turicata* (Acari: Ixodida: Argasidae) (*fide* Wenzel and Tipton 1966. Ectoparasites of Panama. Field Mus. Nat. Hist. Chicago, Illinois. 861 pp.). Voucher specimens of *O. turicata* were deposited in the arachnid collection of the Museum für Natukunde Berlin (ZMB), Germany. *Ornithodoros turicata* is a burrow-dweller known to inhabit burrows of the Gopher Tortoise, *Gopherus polyphemus* (e.g., Beck et al. 1986. J. Med. Entomol. 23:313–319). Additionally, *O. turicata* is reported as a vector of the relapsing or tick-born fever (TBRF), which is caused by several *Borrelia* species that are transmitted to humans by bites of this soft tick species (e.g., Dworkin et al. 2008. Infect. Dis. Clin. North Am. 22:449–68). The fact that *O. turicata* was found over a linear distance of about 780 km from north to south, on the Pacific as well as on the Gulf side, indicates that this tick species occurs throughout the Baja California peninsula.

ALEXANDER GUTSCHE, Humboldt-Universität zu Berlin, Institute for Biology, Invalidenstrasse 43, 10115 Berlin, Germany (e-mail: alexandergutsche@web.de); **FRANK MUTSCHMANN**, Exomed, Erich Kurz Strasse 7, 10319 Berlin, Germany (e-mail: mutschmann@exomed.de).

***CROTALUS MITCHELLII* (Speckled Rattlesnake). ARBOREAL BEHAVIOR.** At 1654 h on 14 May 2004, we observed an adult *Crotalus mitchellii* (sex undetermined) approximately 1 m above the ground in *Opuntia ramosissima* (Diamond or Pencil Cholla) in Granite Cove, Granite Mountains, San Bernardino Co., California, USA (34.7814°N, 115.6537°W, datum WGS 84; elev. 1276 m). Air temperature at the time of observation was 26.2°C. At first observation, the snake was in a coiled position in the cactus, rattling loudly. Upon being photographed, it uncoiled and began to move (Fig. 1). The snake was not collected, and within one hour, the snake had left the cactus.

To our knowledge, few records of arboreal behavior exist for this species, at heights of 0.46 m, 0.76 m, and 0.91 m (Klauber 1997. Rattlesnakes: their habits, life histories, and influence on mankind. Univ. California Press, Berkeley. 1580 pp.). Klauber (*op. cit.*) suggested that rattlesnakes climb more often in pursuit of prey than for refuge from predators or heat. Moore (1978. Copeia 1978:439–442.) showed that *C. m. pyrrhus* in the West Mojave Desert of California exhibit diurnal activity from April–May and October–November, feeding on the only diurnal mammalian prey available at the study site: *Ammospermophilus* (*Citellus*) *leucurus* (Antelope Ground Squirrel). *Ammospermophilus leucurus* are known to climb Pencil Cholla and other cacti and are found at the site of our *C. mitchellii* observation. Given the time of day and time of year, the subject of our observation likely climbed the cactus in pursuit of prey.

FIG. 1. *Crotalus mitchellii* in *Opuntia ramosissima* in the east Mojave Desert of California.

COLOR REPRODUCTION SUPPORTED BY THE THOMAS BEAUVAIS FUND

We thank Harry Greene for identifying the snake and encouraging publication of the observation.

LAURELIN EVANHOE, Department of Ecology and Evolutionary Biology, Corson Hall, Cornell University, Ithaca, New York 14853, USA; **MATTHEW C. HAUG**, Department of Philosophy, College of William and Mary, P.O. Box 8795, Williamsburg, Virginia 23187, USA.

***CROTALUS OREGANUS HELLERI* (Southern Pacific Rattlesnake). DIET.** On 24 April 2010, at 1530 h, we collected an adult *Crotalus oreganus helleri* (total length = 127cm; 552.7 g), in Los Angeles Co., California, USA (34.478°N, 118.510°W; datum: NAD27). Upon capture, we noticed that the snake had consumed a large prey item. Once dissected, an adult California Thrasher (*Toxostoma redivivum*; 86.5 g) was removed from the snake. Positive identification of the prey item was made by L. Comrack. Because the prey item displayed no signs of digestion, we concluded that the bird had been recently consumed and was probably captured alive.

Snakes frequently prey upon eggs and nestlings of various bird species (Stake et al. 2005. J. Herpetol. 39:215–222; Tweit 1996. The Birds of North America. Cornell Lab of Ornithology, Ithaca. 20 pp.; Tyler 1986. Bull. Okla. Ornithol. Soc. 19:14–15); predation upon adult birds is less well-documented. Although snakes are listed as possible predators of juvenile *T. redivivum* (Cody 1998. *In* Poole [ed.], The Birds of North America Online. Cornell Lab of Ornithology, Ithaca), species-specific accounts have not been previously documented. To our knowledge, this is the first documentation of predation on *T. redivivum* by *C. o. helleri*. A digital photograph of the prey item and the specific account data is deposited in the Natural History Museum of Los Angeles County Ornithology Department.

TIM E. HOVEY, California Department of Fish and Game, 21729 Canyon Heights Circle, Santa Clarita, California 91390, USA (e-mail: Thovey@dfg.ca.gov); **LYANN A. COMRACK**, California Department of Fish and Game, 1812 9th Street, Sacramento, California 95811, USA (e-mail: lcomrack@dfg.ca.gov).

***DIADOPHIS PUNCTATUS PUNCTATUS* (Southern Ring-necked Snake). MAXIMUM SIZE.** On 19 May 2008, a female *Diadophis punctatus* was captured crossing the upper loop of the Carrick

Creek nature trail at Table Rock State Park, Pickens, Pickens Co., South Carolina, USA. The snake weighed 27 g and had an SVL of 47 cm. The total length (TL) was 52 cm but it should be noted the snake was missing part of its tail. Nevertheless, this TL exceeds the maximum recorded TL of 48.2 cm for *D. p. punctatus* (Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Institution Press, Washington D.C. 680 pp.). The specimen showed characteristics of *D. p. punctatus*, including uniform mid-ventral spots, but had an unbroken neck ring, suggesting some intergradation with *D. p. edwardsii*. The snake was photographed and released at site of capture.

JEFFREY R. MOHR, Clemson University, Department of Forestry and Natural Resources, 261 Lehotsky Hall, Clemson, South Carolina 29634, USA (e-mail: jmohr@clemson.edu); **BENJAMIN S. STEGENGA**, and **SCOTT A. STEGENGA**, Table Rock State Park, 158 East Ellison Lane, Pickens, South Carolina 29671, USA.

***DIPSADOBOA AULICA* (Marbled Tree Snake). DIET.** *Dipsadoboa aulica* is a small arboreal snake found in southeast Africa. It feeds nocturnally on anurans, geckos, and occasionally skinks and small rodents (Branch 1998. Field Guide to Snakes and Other Reptiles of Southern Africa. Struik, Cape Town. 400 pp.) but has not been documented to prey upon chameleons. At 1130 h on 10 January 2006, we collected a dead adult male *D. aulica* (SVL = 45.9 cm; total length = 58.4 cm) on a tar road (28.11889°S, 32.54667°E, datum: WGS84) near the village of St. Lucia in KwaZulu-Natal, South Africa. The snake had been run over at midbody and two undigested female *Bradypodion setaroi* (Setaro's Dwarf Chameleon) were partly visible extruding from the digestive tract (Fig. 1). Dissection revealed the head of the smaller chameleon (SVL = 5.1 cm; total length = 9.2 cm) in the hindgut of the snake. The larger *B. setaroi* (SVL = 6.6 cm; total length = 11.8 cm) was swallowed tail-first. *Bradypodion* is a South African endemic composed of at least 15 species generally restricted to small, allopatric distributions. *Bradypodion setaroi* is limited to subtropical coastal forests in the northeastern part of the country (Tolley and Burger 2007. Chameleons of Southern Africa. Struik, Cape Town. 400 pp.) and is currently listed as Endangered (EN B1+2c, 2006 IUCN Red List of Threatened Species); however, the species is to be down-listed to Least Concern in 2010 (W. Branch, pers. comm.).

FIG. 1. Road-killed *Dipsadoboa aulica* with two *Bradypodion setaroi* protruding from the digestive tract.

JONATHAN K. WARNER, School of Biological and Conservation Sciences, University of KwaZulu-Natal, Private Bag X01, Scottsville, Pietermaritzburg 3209, South Africa (e-mail: jonathan.k.warner@gmail.com); **GRANT M. BURDEN**, P.O. Box 1144, Arusha, Tanzania (e-mail: grant.burden@gmail.com).

FIG. 1. *Drymarchon melanurus erebennus* feeding on an Evening Bat (*Nycticeius humeralis*).

***DRYMARCHON MELANURUS EREBENNUS* (Texas Indigo Snake). DIET.** *Drymarchon melanurus erebennus* is a large, diurnal colubrid distributed across southern Texas in the United States southward throughout eastern Mexico to the state of Veracruz (McCranie 1981. Cat. Amer. Amphib. Rept. 267:1–4). While mostly terrestrial, it will occasionally climb into bushes and low branches of trees. An active forager, it preys on a wide variety of vertebrates including frogs, fishes, turtles, snakes (including venomous species), birds, and rodents (Wright and Wright 1957. Handbook of Snakes of the United States and Canada. Cornell Univ. Press, Ithaca, New York. 564 pp.; Werler and Dixon 2000. Texas Snakes: Identification, Distribution, and Natural History. Univ. Texas Press, Austin. 519 pp.). Herein we report the first record of predation by *D. m. erebennus* on a bat.

At 1708 h on 25 October 2008, at Southmost Preserve, Cameron Co., Texas, USA, we captured an adult *D. m. erebennus* (total length = 90.5 cm) in a ditch alongside a path adjacent to a large lagoon. The snake was in an area of abundant plant litter and in low light, so it was not immediately evident that the snake had a prey item in its mouth. However, upon closer examination we discovered the snake was attempting to ingest a bat. The bat's body was entirely within the snake's mouth with only the wings protruding (Fig. 1). Unfortunately, during the process of photographing the snake, it regurgitated the bat (which was still alive, albeit mortally injured). The bat was identified as an Evening Bat (*Nycticeius humeralis*; verified by Maxwell Pons, Jr.). *Nycticeius humeralis* roost in tree hollows and behind loose bark and forage in the early evening (Schmidly 2004. The Mammals of Texas. Univ. Texas Press, Austin. 501 pp.). It is likely the snake encountered the bat in a low level roosting area or emerging from it.

RANDY L. POWELL (e-mail: randy.powell@tamuk.edu), **WILLIAM D. LUKEFAHR**, **LAWRENCE T. PALREIRO, JULIO A. QUINTANILLA**, and **GAVINO M. VILLESCAS**, Department of Biological and Health Sciences (MSC 158), Texas A&M University-Kingsville, Kingsville, Texas 78363, USA.

***EPICRATES CENCHRIA* (Rainbow Boa). DIET.** *Epicrates cenchria* occurs in the Atlantic rainforest biome of Brazil from Rio de Janeiro to Pernanbuco. The diet of *E. cenchria* includes small mammals, lizards, bird and their eggs, amphibians, and bats (Freitas 2003. Serpentes Brasileiras. Editoria DALL, Bahia, Brazil. 78 pp.). On 19 January 2009, an adult *E. cenchria* (178 mm total

length) was captured alive by a rural worker in Aparecidinha, Santa Teresa, Espirito Santo, Brazil, and brought to the Museu de Biologia Prof. "Mello Leitão," located in the same city. According to the worker, the snake was found in a hen house and had ingested seven domestic chicken (*Gallus gallus*) chicks. The snake was released several days later. This new diet record for *E. cenchria* represents an additional example of conflict between native and domestic wildlife. *Epicrates cenchria* is widely feared and frequently killed in rural areas of Brazil because of a misconception that it is venomous. In some cases the presence of domestic animals may attract native predators, putting them at risk from human persecution.

IKAEL MANSUR MARTINELLI, Setor de Zoologia, Museu de Biologia Prof. "Mello Leitão," Avenida José Ruschi, 4, CEP 29650-000, Santa Teresa, Espírito Santo, Brazil; e-mail: mansurmartinelli@yahoo.com.br.

***EPICRATES CHRYSOGASTER CHRYSOGASTER* (Turks Island Boa). DIET.** *Epicrates chryogaster chrysogaster* has been reported to feed on small introduced rodents such as rats and mice (*Rattus*, *Mus*), as well as the chicks and eggs of introduced birds such as chickens (*Gallus*; Schwartz and Henderson 1991. Amphibians and Reptiles of the West Indies: Descriptions, Distributions, and Natural History, Univ. Florida Press, Gainesville. 720 pp.; Tolson and Henderson 1993. The Natural History of West Indian Boas, R&A Publishing, Taunton, Somerset, England. 68 pp.), though native lizards probably also factor heavily in the diet. The previous authors report that juvenile *E. c. chrysogaster* are probably saurophagous, but here we report that adults may be entirely saurophagous on small islands without *Rattus*, *Mus*, or *Gallus*. In addition, no previous studies have identified the species of lizards that are preyed upon by *E. chrysogaster*.

AT 0935 h on 8 August 2008, we found an adult male *E. c. chrysogaster* which had recently consumed a medium sized (SVL ca. 65 mm) *Leiocephalus psammodromus* (Turks and Caicos Curly-tailed Lizard). The snake was found on a small island on the Turks Bank, Turks and Caicos Islands. While the food item was not extracted entirely in order to prevent harm to the snake, we were able to determine the species of lizard that had been consumed. Additionally, herpetological surveys have determined that only three species of lizards inhabit the island: the *Anolis scriptus scriptus* (Southern Bahamas Anole), *Leiocephalus psammodromus* (Turks and Caicos Curly-tailed Lizard), and *Sphaerodactylus underwoodi* (Turks Dwarf Gecko). Of these, only *L. psammodromus* reaches sufficient size to have been the size of the food item. As no known record of *Mus*, *Rattus*, or *Gallus* exists for this island, it is expected that lizards are a major, if not the sole, component of the diet of this small population of *E. chrysogaster*.

R. GRAHAM REYNOLDS (e-mail: rgraham@utk.edu) and **MATTHEW L. NIEMILLER** (e-mail: mniemill@utk.edu), Department of Ecology and Evolutionary Biology, University of Tennessee, Knoxville, Tennessee 37996, USA.

***EPICRATES CHRYSOGASTER CHRYSOGASTER* (Turks Island Boa). MAXIMUM SIZE.** To our knowledge, the previously reported maximum size for *Epicrates chrysogaster chrysogaster* is 1310 mm SVL (Schwartz and Henderson 1991. Amphibians and Reptiles of the West Indies: Descriptions, Distributions, and Natural History, Univ. Florida Press, Gainesville. 720 pp.; Tolson and Henderson 1993. The Natural History of West Indian Boas, R&A Publishing, Taunton, Somerset, England. 68 pp.). At 1852 h on 12 August 2008, we found an adult female *E. chrysogaster* which we determined to be 1321 mm SVL by measuring the body with a length of string strung along the spine. The snake was found on North Caicos, Turks and Caicos Islands, about 2.25 km WNW of the town of Kew. The individual weighed 525 g and had a tail length of 228 mm.

In addition, an unusually large captive *E. chrysogaster*, maintained for educational purposes by the Turks and Caicos National Trust, was measured and is reported here to illustrate even larger size that may be reached by this species in captivity. The individual, a female, measured 1540 mm SVL, with a mass of 1100 g, and a tail length of 228 mm. The boa was excavated in the town of Kew, North Caicos, Turks and Caicos Islands during home remodeling and was brought to BNM by the property owner. It had been in captivity for approximately three years prior to our examination, which was performed on 12 August 2008.

R. GRAHAM REYNOLDS (e-mail: rgraham@utk.edu), **MATTHEW L. NIEMILLER** (e-mail: mniemill@utk.edu), Department of Ecology and Evolutionary Biology, University of Tennessee, Knoxville, Tennessee 37996, USA; **BRYAN NAQQI MANCO**, Department of Environment and Coastal Resources, Providenciales, Turks and Caicos Islands (e-mail: naqqi@aol.com).

***EUNECTES NOTAEUS* (Yellow Anaconda). DIET / CANNIBALISM.** *Eunectes notaeus* is a marsh dwelling boid that preys upon a variety of vertebrates (Strüssmann 1997. Biociencias 5:35–52; Waller et al. 2001. Herpetol. Rev. 32:47). The implementation of a harvest program for this species in the Province of Formosa (Argentina), allowed us to evaluate the stomach contents of large numbers of specimens harvested each year from the highly productive floodplain that is seasonally inundated by the Pilcomayo River, Fortín Soledad, Bañado La Estrella, (24.1453°S, 60.6932°W, datum: WGS84). At this location *E. notaeus* is abundant and mainly feeds on waterfowl, bird eggs, aquatic rats, and the common and large *Hydrodynastes gigas* (False Water Cobra; Waller et al. 2007. *In* Henderson and Powell [eds.], Biology of the Boas and Pythons, pp. 340–362. Eagle Mountain Publishing, Utah).

On 3 June 2009, a hunter caught a female *E. notaeus* (SVL = 253 cm; 15 kg). The snake was in excellent body condition showing ovarian follicles in secondary vitellogenesis. In its stomach we found a freshly caught female conspecific (Fig. 1), as well as feathers of a Cormorant (*Phalacrocorax brasilianum*) and the digested remnants of a medium-sized but unidentified bird. This finding represents the first record of cannibalism in *E. notaeus*. The ingested anaconda was immature, 125 cm SVL and though it was not weighted, its size corresponds to an average 1.6 kg specimen (T. Waller, unpubl. data). Moreover, its subsequent dissection revealed a recently ingested juvenile aquatic rat (*Holochilus chacarius*; total length = 205 cm; ca. 35 g), showing that both snakes, predator and prey, were actively feeding.

Rivas and Owens (Herpetol. Rev. 31:45–46) found that large female *E. murinus* from the Venezuelan Llanos often prey upon smaller conspecifics, especially males, during the dry season. He suggested that this behavior could be a strategy to improve their survival during the long fasting periods of pregnancy. However, it is unlikely that such a behavior would be necessary at our highly productive study site, where prey availability does not seem to be a limiting factor for *E. notaeus* and reproductive females are generally in good condition year after year (Waller et al. 2007, *op. cit.*). Instead, this event may have been instigated by both snakes

FIG. 1. Dissection of an adult female *Eunectes notaeus* revealed ingestion of an immature conspecific female (shown here).

attempting to swallow the same prey. This also seems unlikely because the disparity in size between snakes would likely result in differences in prey size selection. Moreover, the absence of another fresh prey item in the stomach if the larger individual, as would be expected in such a situation, argues against accidental ingestion. Another explanation could be that the larger snake was attracted and confused by the scents left on the body of the smaller individual by the recently eaten rat; but again, it is hard to imagine that a large female anaconda would pursue the scent of such a small rodent (35 g) as prey. Regardless of the circumstances, this is the first time in nine years of work that we have received a reliable record of cannibalism by *E. notaeus*, suggesting that the phenomenon is unusual at this location.

We acknowledge Fundación Biodiversidad - Argentina, and the Switzerland Veterinary Office for supporting our research.

MARIANO M. BARROS (e-mail: barros.mariano@gmail.com), **JUAN F. DRAQUE** (e-mail: juandraque@yahoo.com.ar), **PATRICIO A. MICUCCI** (e-mail: marpat.m@gmail.com), and **TOMAS WALLER** (e-mail: twaller@fibertel.com.ar), Fundación Biodiversidad-Argentina, Juncal 754, 7th Floor "60", C1062ABD Buenos Aires, Argentina.

***HELICOPS ANGULATUS* (South American Watersnake). DIET.** *Helicops angulatus* is a semi-aquatic and primarily nocturnal dipsadid snake that is widely distributed in northern South America. This species inhabits ponds, streams and rivers (Ford and Ford 2002. Carib. J. Sci. 38:129–132), where it is known to feed on amphibian eggs, adult frogs, and aquatic lizards, but primarily on fish and tadpoles of the genera "*Hyla*" and *Osteocephalus* (Martins and Oliveira 1998. Herpetol. Nat. Hist. 6:78–150).

On 16 May 2009, at ca. 1600 h, an adult female *H. angulatus* (SVL = 490 mm; tail length = 215 mm) was collected near the Unini river's south margin (01.7116°S, 62.8220°W; datum: WGS 84), Barcelos, Amazonas, Brazil. Upon capture, a Cane Toad (*Rhinella marina* = *Bufo marinus*) tadpole was removed from the mouth of the snake. The *H. angulatus* was deposited in the herpetological collection of Instituto Nacional de Pesquisas da Amazônia (INPA-H 25379). Upon dissection, we found another seven *R. marina* tadpoles inside the snake's stomach. All tadpoles collected were below the developmental stage 25 (Gosner 1960. Herpetologica 16:183–190).

Rhinella marina is known to be toxic and unpalatable to a wide range of predators, but a recent study showed a decrease of both toxin diversity and concentration during its tadpole stage (Hayes et al. 2009. J. Chem. Ecol. 35:391–399). Moreover, several other snake species within the subfamily Xenodontinae prey on adult toads and are able to tolerate bufonid toxins (Duellman and Trueb 1986. The Biology of Amphibians. McGraw-Hill Inc., New York. 670 pp.). Future research should investigate whether *H. angulatus* is also able to tolerate bufonid toxins found in adults, or if consumption of *R. marina* by this snake is restricted to the more palatable tadpole stage.

We thank Albertina P. Lima and Niro Higuchi for providing us with field opportunities at Rio Unini, and Anderson S. Bueno for providing suggestions on this note.

IGOR LUIS KAEFER (e–mail: igorkaefer@hotmail.com) and **ANELISE MONTANARIN** (e-mail: aneta_bio@yahoo.com.br), Coordenação de Pesquisas em Ecologia, Instituto Nacional de Pesquisas da Amazônia, CP 478, 69011-970, Manaus, Amazonas, Brazil.

***HETERODON NASICUS* (Western Hog-nosed Snake). DIET AND ARBOREAL FORAGING BEHAVIOR.** *Heterodon nasicus* is a fossorial snake that primarily inhabits well drained, sandy grasslands of the Great Plains in the United States (Conant and Collins 1991. Reptiles and Amphibians Eastern/Central North America. Houghton Mifflin, Boston, Massachusetts. 450 pp.) *Heterodon nasicus* are known to burrow and forage along the ground for amphibians, reptiles, mammals, and birds, and their offspring, including eggs (Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Press, Washington DC. 680 pp.). Herein, we describe arboreal foraging behavior of *H. nasicus*, including predation upon eggs of *Chondestes grammacus* (Lark Sparrow).

On 7 July 2008 at 2130 h, a pair of *C. grammacus* was discovered jumping and screeching around their nest. The nest was located 1.5 m high in a Chokecherry (*Prunus virginiana*) bush near Keystone Lake on Cedar Point Biological Station, Keith Co, Nebraska, USA (41.2110°N, 101.6574°W, datum: WGS84). Upon approaching the nest, an *H. nasicus* was discovered consuming eggs inside the nest, while being harassed by the sparrows. The birds appeared not to harm the snake, despite making physical contact with the snake's posterior end. After 3–5 min of harassment, the sparrows drove the snake away, but not before the snake grabbed another egg in its mouth. The snake awkwardly, but quickly (i.e., almost a controlled fall), undulated down the dense vegetation and moved 5 m away from the nest, underneath the bark of a fallen Eastern Cottonwood (*Populus deltoides*). The snake finished consuming the second egg under this cover. After 10 min, the snake (female; total length = 67 cm) was captured and when palpated, two eggs were found in her stomach. Upon discovery the snake performed a typical defensive display (Ernst and Ernst, *op. cit.*), but did not regurgitate the eggs. The snake was subsequently released under the same Eastern Cottonwood bark refugia. To our knowledge, this is the first record of arboreal foraging in *H. nasicus* and the first record of *C. grammacus* eggs in this species' diet.

GABRIEL J. LANGFORD (e-mail: farancia@gmail.com), and **JOHN JANOVY, JR.** (e-mail: jjanovy@unlserve.unl.edu), School of Biological Sciences, University of Nebraska-Lincoln, Lincoln, Nebraska 68588, USA.

***HETERODON PLATIRHINOS* (Eastern Hog-nosed Snake). MAXIMUM SIZE.** On 8 April 2010 a melanistic adult female *Heterodon*

platirhinos was captured alive on Fort Stewart Rd. 70B, Fort Stewart, Bryan Co., Georgia, USA (32.0681°N, 81.5569°W, datum: WGS 1984). The snake was measured independently by two teams of experienced herpetologists, who differed in their total length measurements by ca. 2 cm; the mean of these measurements was SVL = 105.9 cm; tail length (tail was intact) = 20.9 cm; total length = 126.8 cm. Mass of the snake was 900 g (no apparent food boli).

The length of this snake exceeds the previously published maximum size (total length = 115.6 cm) for the species (Conant and Collins 1998. A Field Guide to Reptiles and Amphibians of Eastern and Central North America. Houghton Mifflin Co., Boston, Massachusetts. 616 pp.), based on a specimen from Beaver Co., Oklahoma reported by Platt (1969. Univ. Kansas Publ. Mus. Nat. Hist. 18:253–420). We deposited a voucher photograph of the specimen in the University of Florida Museum of Natural History Herpetology Collection (UF 157500).

We thank Kevin Stohlgren and Elizabeth Schlimm for their help measuring and photographing the specimen.

STEVENSON**, Project Orianne Ltd., Indigo Snake Initiative, 414 Club Drive, Hinesville, Georgia 31313, USA.

***HETERODON SIMUS* (Southern Hog-nosed Snake). DIET.** *Heterodon simus* is commonly reported to feed "almost exclusively" on anurans (Mount 1975. The Reptiles and Amphibians of Alabama. Agriculture Experiment Station, Auburn University. 345 pp.; Tuberville and Jensen 2008. *In* Jensen et al. [eds.], Amphibians and Reptiles of Georgia, Univ. Georgia Press, Athens. 575 pp.). Beane et al. (1998. Herpetol. Rev. 29:44–45) also reported two lizard species as prey. Here we report predation by *H. simus* on a large invertebrate.

An adult male *H. simus* (SVL = 330 mm; total length = 408 mm) was found road-killed ca. 9.7 km WNW of Wagram, Scotland Co., North Carolina, USA (34.904579°N, 79.470070°W, datum: WGS 84) on 4 October 2008. The stomach contained a third (final) instar Ox Beetle (*Strategus antaeus*) larva. The larva was too badly fragmented to measure accurately, but was estimated to be ca. 60 mm total length. Insect fragments are occasionally found in the digestive tracts and in the feces of *H. simus* (pers. obs.), but virtually all these almost certainly represent items secondarily ingested along with typical food items (e.g., *Scaphiopus*, *Bufo*). The large size of this grub, its only partially digested condition and lack of association with any recently ingested vertebrate prey, and its presence in the stomach rather than farther down the digestive tract indicate that it was almost certainly taken directly as prey and not secondarily ingested. A few tarsal bone fragments from an anuran of undetermined species were also present in the stomach, but they were obviously from a prey item that had been eaten much earlier. To our knowledge, this represents the first documentation of an invertebrate taken as primary prey by *H. simus*. The *H. simus* specimen is deposited in the herpetological research collections of the North Carolina State Museum of Natural Sciences (NCSM 74482). The *S. antaeus* remains are deposited in the entomological collections of North Carolina State University.

MESSENGER**, 2715 Vanderbilt Avenue, Raleigh, North Carolina 27607, USA (e-mail: herpsrule2@aol.com); **DAVID L. STEPHAN**, Dept. of Entomology, Box 7613, North Carolina State University, Raleigh, North Carolina 27695-7613, USA (e-mail: david_stephan@ncsu.edu).

***LAMPROPELTIS GETULA HOLBROOKI* (Speckled Kingsnake). DIET.** *Lampropeltis getula* eat a variety of prey, including small mammals, birds, eggs, and other reptiles. Many species of snakes are eaten by *L. getula*, but the only species of watersnakes noted are *Nerodia erythrogaster*, *N. fasciata*, *N. floridana*, and *N. rhombifer* (Clark 1949. J. Tennessee Acad. Sci. 24:244–261; Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Institution Press, Washington D.C. 668 pp.; Winne et al. 2007. Copeia 2007:507–519). No previous reports include *L. g. holbrooki* preying on *Nerodia cyclopion*.

On 23 March 2007, a *L. getula* (female; SVL = 89.1 cm; tail length = 12.8 cm; 288 g) was found constricting a *N. cyclopion* (male; SVL = 63.2 cm; tail length = 14.0 cm; 150 g) at Spanish Lake, Cade, Iberia Parish, Louisiana, USA. The *L. getula* had approximately 3½ loops wrapped around the anterior half of the prey, but released the watersnake when disturbed. The watersnake had been constricted tightly, but was still capable of slight movement. When the watersnake became responsive and alert, it was released at the site of capture. If ingestion had been allowed, this would have been a 52.1% prey mass/predator mass ratio.

SCHUYLER F. DARTEZ, PAUL M. HAMPTON, NICHOLAS E. HAERTLE, Department of Biology, University of Louisiana at Lafayette, 300 East St. Mary St. Lafayette, Louisiana 70504, USA; **CAROLINA S. MONTEIRO**, Center for Ecology and Environmental Technology, 703 Thoroughbred Dr., Lafayette, Louisiana 70507, USA.

***LEPTOPHIS DIPLOTROPIS* (Pacific Coast Parrot Snake). DIET.** *Leptophis diplotropis* is a colubrid endemic to México that feeds on a variety of frogs (Hardy and McDiarmid 1969. Univ. Kansas Publ. Mus. Nat. Hist. 18:182; Oliver 1948. Bull. Amer. Mus. Nat. Hist. 92:255). Although lizards are included in the diet of other species within the genus (Henderson 1982. Amphibia-Reptilia 3:71–80; Henderson et al. 1977. J. Herpetol. 11:231–232), to our knowledge no lizards have been reported in the diet of *L. diplotropis*. Here we present the first record of a lizard in the diet of this species.

On 13 November 2009, at 1344 h, an adult *L. diplotropis* was observed in the process of feeding on a *Phyllodactylus tuberculosus* at Campamento Aserradero, María Madre Island, Nayarit, México (21.6801°N, 106.6054°W, WGS84; elev. 41 m). The snake and prey were found on the ground near a wooden table used for remodeling buildings. At this site, geckos often seek shelter between the construction materials, where they are hunted by snakes. When encountered, the snake was holding its prey by the posterior body portion. It proceeded to swallow the lizard over the next 13 min. The event was photographed and a color slide (MFSI-REPT-859) was deposited in the amphibian and reptile collection of Museo de las Ciencias Biológicas "Enrique Beltrán," FES-Iztacala, Universidad Nacional Autónoma de México, México.

We thank Robert W. Henderson for kindly providing literature.

ALFONSO HERNÁNDEZ-RÍOS, Laboratorio de Ecología, Facultad de Estudios Superiores Iztacala, Universidad Nacional Autónoma de México, Estado de México 54090, México (e-mail: fermento_etereo@hotmail.com); **JUAN CRUZADO-CORTÉS**, 21 de marzo #406, Colonia El Terrero, Santiago, Nuevo León, México (e-mail: cruzadojuan@hotmail.com).

***MASTICOPHIS* (= *COLUBER*) *MENTOVARIUS* (Neotropical Whipsnake). DIET.** Species in the genus *Masticophis* are known to prey on a diversity of vertebrates, including young birds, lizards, frogs, rodents, eggs, snakes, and small turtles (Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Institution Press, Washington D.C. 668 pp.; Werler and Dixon 2000. Texas Snakes: Identification, Distribution, and Natural History. Univ. Texas Press. Austin. 437 pp.). *Masticophis mentovarius*, like all members of the genus, is considered a generalist forager. On 1 December 2008, in tropical dry forest at Las Mojarras, Municipality of Oaxaca de Juárez, Oaxaca, México (17.11186°N, 96.72225°W; datum: WGS84; elev. 1683 m), we observed a male *M. mentovarius* feeding on a Grayish Mouse Opossum (*Tlacuatzin canescens*; Fig. 1). This is the first record of a marsupial in the diet of *M. mentovarius*.

We thank the Ejido Guadalupe Victoria and Oaxaca de Juarez Municipality authorities and the colleagues from the Unidad de Gestión Ambiental (UGA) for their support. We also thank the project "Diversidad Biológica del Estado de Hidalgo" 43761.

COLOR REPRODUCTION SUPPORTED BY THE THOMAS BEAUVAIS FUND

***MASTIGODRYAS BRUESI* (Windward Tree Racer, White Snake). BEHAVIOR.** *Mastigodryas bruesi* is native to the Grenada and St. Vincent island banks and has been introduced on Barbados (Greene et al. 2003. Cat. Amer. Amphib. Rept. 777:1–3). Very little is known about the biology of the species (Henderson and Powell 2009. Natural History of West Indian Reptiles and Amphibians. Univ. Press Florida, Gainesville. xxiv + 495 pp.). From 3–22 June 2010, we had 32 encounters with *M. bruesi* on Union Island (St. Vincent and the Grenadines). These snakes were abundant at elevations ranging from sea level to nearly 300 m (just below the highest point on the island) and in a variety of habitats. The number of encounters and the broad distribution of *M. bruesi* on Union might be attributable to the absence of the Small Indian Mongoose (*Urva auropunctata*), which has been implicated in the extirpation or extinction of several species of ground-dwelling lizards and snakes in the West Indies (e.g., Powell and Henderson 2005. Iguana 12:62–77). Encounters with *M. bruesi* on St. Vincent and Grenada are comparatively rare and mongooses are common. On the larger mongoose-infested islands, arboreal, nocturnally active boids (*Corallus grenadensis* and *C. cookii*) have broad distributions at elevations under 500 m and can be encountered in a variety of habitats (Henderson 2002. Neotropical Treeboas: Natural History of the *Corallus hortulanus* Complex. Krieger Publ. Co., Malabar, Florida. xiv + 197 pp.; Powell et al. 2007. *In* Henderson and Powell [eds.], Biology of the Boas and Pythons, pp. 374–387. Eagle Mountain Publ., Eagle Mountain, Utah). In contrast, diurnally active and largely ground-dwelling *M. bruesi* is rarely encountered outside of disturbed areas where human activity is common and mongooses rare or absent. On mongoose-free Union, the frequencies of encounters with *C. grenadensis* and *M. bruesi* encounters were comparable.

Although 26 of 28 diurnal encounters were with individuals on the ground and two with snakes in rock crevices, *M. bruesi* is an excellent climber. Of 14 escapes we observed, 10 individuals fled downhill before ascending into shrubs or vines that they then used to gain access to the lower branches of larger trees. Arboreality might provide some protection from terrestrial predators (e.g., mongooses; Sajdak and Henderson 1991. Oryx 25:33–38). The other four snakes escaped by continuing downhill until out of sight or by entering rock crevices. When captured, snakes were not aggressive and seldom attempted to bite. In all instances, they released musk in an apparent effort to deter handling. Four snakes vibrated their tails when cornered or captured.

Three *M. bruesi* were encountered while actively foraging, probing and tongue-flicking in leaf litter and rock crevices where geckos (e.g., *Gonatodes daudini* and *Sphaerodactylus kirbyi*) occurred. They also responded actively to movements. Three individuals followed and struck at small rocks rolling downhill. We observed four snakes sleeping in trees at night while coiled on branches at heights of 2–8 m. Schwartz and Henderson (1991. Amphibians and Reptiles of the West Indies: Descriptions, Distributions, and Natural History. Univ. Florida Press, Gainesville. xvi + 720 pp.) noted that *M. bruesi* sleeps at heights of at least 5 m.

Permits to conduct research on Union Island were issued by Brian Johnson, Director, Department of Forestry, St. Vincent and the Grenadines. Protocols were approved by the Avila University Animal Care and Use Committee. Fieldwork was funded by a grant from the National Science Foundation (USA) to Robert Powell (DBI-0851610).

MEL JOSÉ RIVERA RODRÍGUEZ, Department of Biology, University of Puerto Rico, Mayagüez, Puerto Rico 00681 (e-mail: melrivera103@yahoo.com); **EHREN J. ***MICRURUS DISTANS* (Sinaloan Coralsnake). DIET.** *Micrurus distans* is an elapid snake distributed from southern Chihuahua and Sonora to central Guerrero, México (Lemos-Espinal and Smith 2007. Amphibians and Reptiles of the State of Chihuahua, México. Universidad Nacional Autónoma de México (UNAM) and Comisión Nacional para el conocimiento y uso de la Biodiversidad (CONABIO), México, D.F. 418 pp.). This species feeds on small snakes, lizards, and frogs (Ramirez-Bautista 1994. Manual y Clave Ilustrada de los Anfibios y Reptiles de la Región de Chamela, Jalisco, México. Instituto de Biología, UNAM, México D.F. 87 pp.), but few specific diet records are known. Here we report evidence of predator-prey interaction between *M. distans* and its presumptive Batesian mimic *Lampropeltis triangulum*.

On the morning of 25 March 2008, in tropical deciduous forest at Chamela UNAM Biological Station, Jalisco, México, we observed an *M. distans* preying on an *L. triangulum* in the leaf litter (Fig. 1). The snakes were of similar size (ca. 700 mm total length) and were observed wrestling, with the *L. triangulum* apparently using constriction as a defensive tactic against its predator. After about 10 min, the *M. distans* immobilized its prey by envenomation and later ingested it headfirst. After approximately 20 min, the *L. triangulum* had been fully ingested and the *M. distans* was hidden among leaf litter.

COLOR REPRODUCTION SUPPORTED BY THE THOMAS BEAUVAIS FUND

FIG. 1. *Micrurus distans* preying on *Lampropeltis triangulum* in Jalisco, México.

SERGIO SANTANA, CUCBA, Universidad de Guadalajara, Carretera a Nogales Km 15.5, Las Agujas Nextipac, Zapopan, Jalisco, México; e-mail: s_r_santana@hotmail.com).

***MICRURUS FULVIUS* (Harlequin Coralsnake). DIET.** The diet of *Micrurus fulvius* consists primarily of elongate reptiles including other snakes (Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Institution Press, Washington D.C. 668 pp.). Previously, only one viperid has been documented as a prey item of *M. fulvius*. A *Sistrurus miliarius* (Pigmy Rattlesnake) was removed by dissection from a *M. fulvius* from the University of Texas at Tyler teaching collection. Locality data for the specimen was not available. The coral snake measured 551 mm SVL with a head width of 10.42 mm. The partially digested prey measured 138 mm in total length and 5.5 mm in diameter at its maximum point. After the prey was removed, the coral snake weighed 37.33 g and the prey weighed 1.88 g. From the remains, the prey generated the conservative estimates of the following prey-to-predator ratios: a weight ratio of 0.05, an ingestion ratio of 0.52, and a length ratio (= total length of prey/snout–vent length of predator) of 0.25. To my knowledge, this is the first report of a *S. miliarius* as a prey item of *M. fulvius*.

PAUL M. HAMPTON, Department of Biology, University of Louisiana at Lafayette, Lafayette, Louisiana 70504, USA. Current address: Department of Biology, Carroll University, Waukesha, Wisconsin 53186, USA.

***MICRURUS NIGROCINCTUS NIGROCINCTUS* (Central American Coral Snake). DIET.** Caecilians are known from the diets of at least nine species of coral snake (Burger 1997. Bull. Chicago Herpetol. Soc. 32:145; Freile and Fletcher-Lazo 2009. Herpetol. Rev. 40:99; Roze 1996. Coral Snakes of the Americas: Biology, Identification and Venoms. Krieger Publ. Co., Malabar, Florida. 340 pp.), with the earliest record dating back to Boulenger (1913. Proc. Zool. Soc. London 1913:1019–1038). Although multiple early authorities recognized interactions between coral snakes and caecilians, the exact species relationships were not always reported; prey were often reported only as "caecilian." *Micrurus nigrocinctus nigrocinctus* is a common member of the genus within its range (Greene and Seib 1983. *In* D. H. Janzen [ed.], Costa Rican Natural History, pp. 406–408. Univ. Chicago Press, Illinois) and has been reported to consume caecilians but until now specific species of caecilians have not been reported. Here we present three independent accounts of *M. n. nigrocinctus* feeding on the caecilian *Oscaecilia ochrocephala*.

On 27 July 2003, at ca. ca. 1700 h, RVH observed a recently killed female coral snake (SVL = 419 mm; total length = 466 mm; 15.8 g after prey removal) in a private lawn in Gamboa, Colon Province, Panama. Closer inspection of the specimen revealed a blow to the upper body caused its death. The specimen appeared to contain a large food item and upon dissection was found to contain an *O. ochrocephala* that had been consumed headfirst (total length = 281 mm; 4.9 g). Both specimens were deposited at the Círculo Herpetológico de Panamá (Fig. 1; CH5730 and CH5732).

On 17 September 2009, at ca. 1130 h, AH collected a coral snake in the Río Agua Salud watershed, El Giral, Colon Province, Panama. After being placed in a bag, the snake regurgitated a partly digested *O. ochrocephala* that had been consumed headfirst. The snake was subsequently released and the caecilian left on site.

On 21 September 2009, at ca. 1330 h, RID observed a *M. n. nigrocinctus* biting an *O. ochrocephala* on a lawn in Parque Municipal Summit, Panama Province, Panama. Upon approach, the coral snake released the caecilian and fled to nearby cover. The caecilian appeared dead, and was moved 2–3 m away from the capture site. Some minutes later, the coral snake returned, appearing to be seeking the dead prey. The coral snake bit the caecilian and started eating it headfirst. At ca. 1400 h, the coral snake was observed swallowing its prey, from a concealed position (Fig. 2). The caecilian was somewhat longer than the snake

FIG. 2. *Micrurus n. nigrocinctus* feeding on an *O. ochrocephala* on a lawn in Parque Municipal Summit, Panama Province, Panama, 21 September 2009.

and consumption took approximately 50 min. No attempt was made to interrupt the feeding event or to collect the snake. Photos from all three observations are available on the Smithsonian Tropical Research Institute's Digital File Manager website at http://biogeodb.stri.si.edu/bioinformatics/dfm/.

Micrurus nigrocinctus nigrocinctus has previously been considered a generalist, consuming a wide range of small amphibian and reptile species. Based on the observations reported here, we think that caecilians might be a more important diet item for this species than previously considered.

ROBERT VINCENT HORAN III, D. B. Warnell School of Forestry and Natural Resources, University of Georgia, Athens, Georgia 30602, USA (e-mail: rvhoran@uga.edu); **ROBERTO IBÁÑEZ-D.**, Smithsonian Tropical Research Institute, Apartado 0843–03092, Balboa, Ancón, Panamá, Rep. de Panamá and Círculo Herpetológico de Panamá, Apartado 0824-00122, Panamá, Rep. de Panamá (e-mail: ibanezr@si.edu); **ANDRÉS HERNANDEZ**, Smithsonian Tropical Research Institute, Apartado 0843–03092, Balboa, Ancón, Panamá, Rep. de Panamá.

***NAJA MELANOLEUCA* (Forest Cobra). DIET AND FORAGING BEHAVIOR.** Primarily an arboreal snake restricted to tropical and subtropical African forests, *Naja melanoleuca* is a dietary generalist that preys on small mammals, anurans, birds, other squamates, and fish (Alexander and Marais 2007. A Guide to the Reptiles of Southern Africa. Struik, Cape Town. 408 pp.). The species is locally abundant in the coastal village of St. Lucia in northeastern South Africa, and is frequently encountered

FIG. 1. *Naja melanoleuca* with regurgitated *Stactolaema leucotis.*

around human residences. The presence of *N. melanoleuca* in trees is often betrayed by the shrieking alarm calls of gregarious birds like the Dark-capped Bulbul (*Pycnonotus tricolor*), White-eared Barbet (*Stactolaema leucotis*), and Weavers (*Ploceus* spp.). Additionally, these birds sometimes engage in a series of mock attacks by making short, diving flights directly at the snake before quickly turning away to avoid contact. On three occasions, I have also observed *N. melanoleuca* coiled on or around small branches make reciprocal lunges with open mouths at birds as they fly past. On the morning of 10 February 2009, after observing part of one such encounter in a residential garden in St. Lucia (28.38293°S, 32.40816°E, datum: WGS84), I captured the snake (branch height = 2.5 m) and examined its stomach contents. The individual (SVL = 144 cm; mass = 984 g) regurgitated six adult *S. leucotis* (Fig. 1) that collectively weighed 361 g (36.7% of snake body mass). Although I did not witness the snake feeding, based on the presence of perturbed *S. leucotis* at the capture scene and the relatively undigested condition of the prey (all ingested head-first), the birds presumably had been eaten immediately before my arrival. *Stactolaema leucotis* sometimes roost communally in tree cavities (Hockey et al. 2005. Birds of Southern Africa, 7th ed. The Trustees of the John Voelcker Bird Book Fund, Cape Town. 1296 pp.), so it is possible the snake trapped the six barbets in a nest prior to feeding. Alternately, *N. melanoleuca* might intentionally expose themselves to some avian prey because the resulting response behavior (mock attacks) by groups of birds puts the snakes in close proximity to multiple meals. *Stactolaema leucotis* has not been previously recorded in the diet of *N. melanoleuca.* Regurgitated stomach contents of other *N. melanoleuca* captured at St. Lucia during 2007–2009 also include an *Acontias plumbeus* (Giant Legless Skink), *Amietophrynus gutturalis* (Guttural Toad), and unidentified small mammals.

***NATRIX MAURA* (Viperine Snake). NON-ACCIDENTAL SALT WATER ACTIVITY.** Snakes in the genus *Natrix* are occasionally found in marine environments but few records substantiate voluntary entry. The earliest record appears to be that of Böse (1897. Zoologischer Anzeiger 20[521]:255), a naval physician aboard the warship S.M.S. Blücher, who reported a *N. natrix* 1 km from the coast of the Second German Empire (1871–1918)

in an unspecified (either the North Sea or Baltic Sea) location. *Natrix natrix* subsequently has been reported in the Atlantic Ocean 46.3 km off the coast of Norway (Hecht 1930. Mitt. Zool. Mus. Berlin 16:345–346), approximately 11 km from the coast of France between Île de Penfret in the Îles de Glénan and the coast (Guérin-Ganivet 1909. Bull. Inst. Oceanographie 132:1–2), and in the Bay of Biscay (p. 227 *in* Smith 1951. The British Amphibians and Reptiles. Collins, London. 318 pp.). Additional records include the North Sea (9.7 km from the coast of Bretagne, France; Hecht 1930. Mitt. Zool. Mus. Berlin 16:345–346) and the English Channel (p. 126 *in* Loveridge 1945. Reptiles of the Pacific World. Macmillan Co., New York. 259 pp.) but it is unclear whether these records reflect accidental or voluntary entry into saline waters.

Natrix tessellata, on the other hand, has been observed chasing small gobies in the Black Sea along the shore near Odessa (Ukraine; p. 164 *in* Boulenger 1913. The Snakes of Europe. Methuen and Company, London. 269 pp.) and a single specimen of *N. maura* was observed in a 0.2 m deep pool on the beach between Tarifa and Algeciras (Cádiz Province, Spain) that is inhabited by small fish and that, at high tide, is flooded with seawater (Cabot and Olea 1978. Doñana, Acta Vertebrata 5:107).

In August, when freshwater streams in southeastern Cádiz Province, Spain, are completely dry, *N. maura* is frequently seen fishing in small "pools" formed by sand and stones in the tidal zone by Piedra de las Morenas (36.07095°N, 5.7500889°W; datum WGS84). Many small fish remain trapped in these pools between low tide and high tide and, on one occasion, an individual that had captured a "cabozo" (*Gobius paganellus*) was seen. During August 1986–1987, while spear fishing in the area of Galerilla (Ensenada de Bolonia, Cádiz Province, Spain; 36.0737083°N, 5.7597778°W; datum WGS84) one of us (RC) observed a *N. maura* actively swimming on the surface of the Atlantic Ocean where water depth was 5 m. These observations confirm that *Natrix maura* engages in limited, non-accidental, activity in salt water.

***NERODIA RHOMBIFER* (Diamond-backed Watersnake). INTERSEXUALITY.** Intersexuality is rare among adult snakes (Cole 1975. *In* Reinboth [ed.], Intersexuality in the Animal Kingdom, pp. 340–355. Springer-Verlag, New York). Adult female *Pseudoficimia frontalis* universally possess hemipenes, though they are smaller than those of males (Hardy 1970. Herpetologica 26:336–343). Adult female *Bothrops insularis* may be either normal or intersexual with most being intersexual. Normal females of this species appear to be sterile while intersexuals are fertile but are capable of carrying fewer embryos than sister taxa (Hoge et al. 1959. Mem. Inst. Butantan 29:17–88). Wilson and Robinson (1971. Bull. So. California Acad. Sci. 70:53–54) described an intersexual *Amastridium veliferum* that apparently functioned as a female though it possessed hemipenes. The hemipenes, however, were reduced in size and were not fully ornamented. An intersexual *Thamnophis sirtalis* was described by Krohmer (1989. Copeia 1989:1064–1068). Upon dissection, this individual possessed male sex characters on the left side and female sex characters on the right, though it was behaviorally only a male.

On 31 August 2007, 19 *Nerodia rhombifer* were collected from a private fish farm in Desha Co., Arkansas, USA (33.67992°N, 91.26831°W, datum: WGS 84). Of these, six were normal males, 12 were normal females, and 1 was an intersexual. The intersexual (SVL = 802 mm, tail length = 223 mm; ASUMZ 30809) lacked the papillae on the chin indicative of male *N. rhombifer*, but possessed hemipenes with full ornamentation (Fig. 1). Dissection showed oviducts and ovaries with pre-vitellogenic follicles and undeveloped Wolffian ducts, thus signifying a female. The right ovary (75 mm × 6 mm) was removed and follicles were measured (N = 6; mean length ± SD = 6.833 ± 1.722 mm; mean diameter ± SD = 3.833 ± 0.983 mm). Because the Wolffian ducts were not developed into ductus deferentia, it appears that this individual could only function as a female, and the abnormality was the possession of hemipenes. This individual is, therefore, considered a pseudohermaphrodite as opposed to a true hermaphrodite.

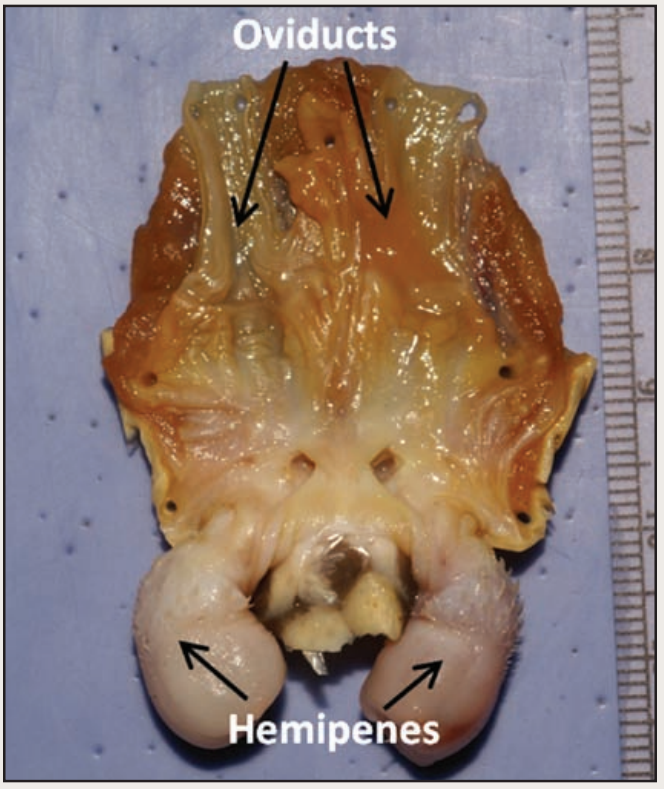

FIG. 1. Dissected cloaca of intersexual *Nerodia rhombifer* showing both male and female reproductive organs.

The cause of sexual abnormalities is not fully understood and both genetic and hormonal factors have been proposed (Hoge et al. 1959, *op. cit.*, Fox 1977. *In* Gans and Parsons [eds.], Biology of the Reptilia, Vol. 6, Morphology E, pp. 1–157. Academic Press, New York). Because our *N. rhombifer* represents a single instance of intersexuality in this species, aberrant hormonal or genetic factors are likely the cause.

JONATHAN W. STANLEY (e-mail: jonathanw.stanley@smail.astate.edu) and **STANLEY E. TRAUTH** (e-mail: strauth@astate.edu), Department of Biological Sciences, Arkansas State University, P.O. Box 599, State University, Arkansas 72467, USA.

***NERODIA SIPEDON* (Northern Watersnake). DEFENSIVE BEHAVIOR.** Many reptiles have the ability to detach their tails when threatened or attacked. This antipredator behavior, called tail autotomy, has been reported for various species of lizards,

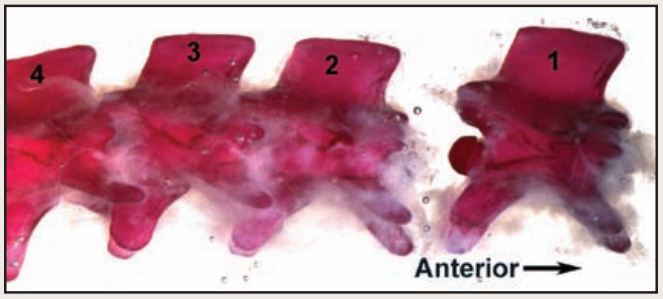

FIG. 1. *Nerodia sipedon* vertebrae caudal to the tail detachment site. Vertebra 1 has been isolated to show it is complete.

sphenodonts, amphisbaenids, and snakes. Among these taxa, an array of tail autotomy strategies exists (Arnold 1984. J. Nat. Hist. 18:127–169). True autotomy occurs when the tail is lost spontaneously and is later regenerated, as is the case with many lizards and *Sphenodon*. Often the tail breaks intravertebrally, along a pre-existing fissure. Pseudoautotomy occurs when a mechanical force is required to separate the tail from the body and the tail does not grow back; this is common in natricine snakes in North America (Cooper 1993. Amphibia-Reptilia 14:86–89; Fitch 1965. Univ. Kansas Publ. Mus. Nat. Hist. 15:493–564; Todd 2010. Amphibia-Reptilia 31:213–215). Pseudoautotomy is further divided into specialized pseudoautotomy where the tail anatomy facilitates breakage, and non-specialized pseudoautotomy where the tail is lost because it is long and fragile with no clear mechanisms to facilitate detachment (Slowinski and Savage 1995. Herpetologica 51:338–341).

At approximately 1130 h on 27 August 2009, we captured an adult *Nerodia sipedon* in Killarney Provincial Park, Ontario, Canada (46.08333°N, 81.33333°W, datum NAD 83). The snake was basking on a granite ledge, roughly 10 m from water's edge. The snake was caught by the tail and it immediately performed a lateral roll, causing its tail to detach. We dropped the tail and caught the snake before it could escape. Very little blood was lost through the wound, where the tail detached. The isolated tail continued to move in response to touch for almost 30 min. The tail was frozen and shipped to Dalhousie University, Nova Scotia, Canada for clearing and staining after fixation in neutral buffered formalin.

The wriggling of the tail immediately after detachment and prolonged response of the tail to touch suggests that these snakes may have anatomical features that facilitate tail detachment for predator evasion. This would fall into the category of specialized tail pseudoautotomy. To determine whether the tail had broken intra- or intervertebrally, the tail tissue was cleared using trypsin powder in sodium tetraborate and potassium hydroxide. The bone was stained with aliziran red. Fig. 1 shows the first four vertebrae after the break site. The first vertebra caudal to the break site is separated to show that it is complete, confirming that the tail broke intervertebrally and that *N. sipedon* displays tail pseudoautotomy in response to a sheer force sufficient to detach the tail. There are no distinctive osteological features before or after the break site, suggesting that anatomically, pseudoautotomy in *N. sipedon* is of a non-specialized nature.

We thank Ryan Kerney and Richard Wassersug for assistance.

OPHIOPHAGUS HANNAH **(King Cobra). DIET.** *Ophiophagus hannah* is a front-fanged elapid snake found throughout much of Southeast Asia. *Ophiophagus hannah* is known to primarily consume other snakes, but has also been documented to consume lizards, including varanids (Evans 1902. J. Bombay Nat. Hist. Soc. 14:409–418; Hesed 2006. Herpetol. Rev. 37:480; Smith 1943. Fauna of British India: Reptilia and Amphibia, Vol. III, Serpentes. Taylor & Francis, London). However, a review of published dietary observations in this species showed all records to be restricted to India, Malaysia, and Thailand (Hesed, *op. cit.*). To our knowledge, this is the first record of a varanid in the diet of *O. hannah* in the Philippines.

During fieldwork in the Philippines, we observed a male *Ophiophagus hannah* (total length = 327.5 cm; 3.75 kg) consuming, head-first, a 1.5 kg *Varanus cumingi* (Fig. 1.). The event occurred on 12 April 2009, in mixed primary and secondary growth forest, on a trail near a water intake system, in Pasonanca Natural Park, Barangay Pasonanca, Zamboanga City Province, Mindanao Island, Philippines (6.9922333°N, 122.0604333°E, datum: WGS-84; elev. 90 m). Both specimens were collected, preserved, and deposited at the Biodiversity Institute, University of Kansas (KU 321813: *Ophiophagus hannah*, KU 321814: *Varanus cumingi*).

COLOR REPRODUCTION SUPPORTED BY THE THOMAS BEAUVAIS FUND

***OPISTHOTROPIS KUATUNENSIS* (Striped Stream Snake). DIET.** *Opisthotropis kuatunensis* is a small- to medium-sized aquatic snake which is widely distributed in southern China, including Fujian, Guangxi, Jiangxi, Zhejiang, Guangdong provinces and Hong Kong Special Administrative Region (Karsen et al. 1998. Hong Kong Amphibians and Reptiles. Provisional Urban Council. Hong Kong SAR. 186 pp.). This snake inhabits moderate- to high-gradient rocky streams on hillslopes with intact forest. It can be observed at night foraging in stream pools and riffles, probing crevices in the substrate for prey. Very limited information is available about its diet except that it consumes fish and tadpoles in captivity (Karsen et al., *op. cit.*). Here we report the first documented observation of *O. kuatunensis* consuming frog eggs and tadpoles in the wild, which also represents the first report of frog egg consumption by any snake in the genus *Opisthotropis*.

At 2105 h on 18 September 2009, at Kadoorie Farm and Botanic Garden (22.43386°N, 114.12736°E, datum: WGS84; elev. 415 m), New Territories, Hong Kong, we observed a female *O. kuatunensis* (SVL = 46 cm; total length = 55 cm) attempting to swallow an egg of *Paa exilispinosa* (Lesser Spiny Frog) in an artificial pond (length × width × depth = 50 × 30 × 18 cm) that was located in secondary forest and was connected to a 2 m wide stream nearby. When the egg was ingested halfway, the snake detected our presence, released the egg, and fled. We caught the snake for measurement and photographic record. A total of 19 eggs of *P. exilispinosa* at early tail-bud stage (Gosner 1960. Herpetologica 16:183–190) were found in the pond. Clutches of *P. exilispinosa* generally contain approximately 50–150 eggs and the entire clutch is typically deposited together in a small pool (N. Karraker, unpubl. data). The few eggs observed at this site suggest that the snake, or possibly some other predator, had consumed other eggs. Eggs of *P. exilispinosa* are approximately 12–23 mm in diameter, with embryos ranging from 9 to 11 mm, depending upon developmental stage (N. Karraker, unpubl. data). These are the second largest embryos of any stream-breeding frog in Hong Kong, aside from those of the Giant Spiny Frog (*P. spinosa*), and their size and oviposition as a group potentially represents a substantial food source for *O. kuatenensis*.

At 2040 h on 11 January 2010, at Tai Mo Shan (22.54278°N, 114.28917°E, datum: WGS84; elev. 878 m), New Territories, Hong Kong, a male *O. kuatunensis* (SVL = 32 cm; total length = 38.5 cm) was observed biting the head of a *Leptolalax liui* (Leaf Litter Toad) tadpole (total length ca. 3 cm) in a pool (length × width × depth = 62 × 30 × 8 cm) along a natural stream in secondary forest. The tadpole struggled and escaped after being held for 30 seconds, and we were unable to capture it. This sighting confirms that *O. kuatunensis* eats tadpoles in the wild. These two species are commonly sympatric in streams in Hong Kong, and it is likely that *L. liui* tadpoles are regular prey for *O. kuatunensis*. Although the natural diets of stream snakes in southern China are largely unknown, amphibians may be important prey here, as they are for stream-associated snakes in other regions of the world.

We thank Kadoorie Farm and Botanic Garden for authorization to conduct field work at the site and N. E. Karraker and M. W. N. Lau for their valuable comments on the manuscript.

***OXYBELIS AENEUS* (Brown Vinesnake). MOVEMENTS AND FORAGING BEHAVIOR.** Monitoring movement patterns in vertebrates is a complex task, especially in secretive species such as snakes (Shine et al. 2006. Copeia 2006:103–115). Radiotelemetry has been used to better understand the ecology of snakes, but has seldom been applied to arboreal slender species or small terrestrial or fossorial species and many ecological aspects of these species are unknown (Madrid Sotelo and Balderas Valdivia 2008. Bol. Soc. Herpetol. Mex. 16:5–12). Here we use radiotelemetry to investigate movement patterns of seven female *O. aeneus* during the dry season in the tropical dry forest of Chamela, Jalisco, México. Additionally, we report observations of foraging behavior in the telemetered snakes.

Seven adult female *Oxybelis aeneus* were captured by hand in the first two weeks of April 2007 in the tropical dry forest around the Chamela Field Station. One radiotransmitter (< 5% of snake mass) model TXA-0061 (Telenax®, Mexico) was attached externally to the back of each individual (Madrid-Sotelo and García 2008. North-West J. Zool. 2:335–338) and the snakes were released at their capture location within 24 h. Between April and June snakes were relocated daily on an alternating morning (1000–1400 h) or afternoon (1600–1900 h) schedule and each snake's location was recorded using a handheld GPS (model Etrex, Garmin). Whenever possible, snake locations were verified visually and the habitat (tree, shrub, or soil) and approximate perch height was recorded. Activity area was estimated using the Movement Animal Extension in Arc View 3.2 (ESRI 1996). We also determined number of significant movements (those >10 m) and the mean movement distance travelled by each snake.

Activity areas were smaller than one hectare in most of the cases (Table 1) and movements were generally small; less than 20% were greater than 10 m. Similarly, the mean distance traveled was less than 30 m (Table 1). Most (88.2%) of all visualized snakes were in trees or shrubs 60 to 130 cm above the ground, whereas 5.9% were higher than 2 m and only 5.9% were located on the ground. On two occasions we observed snakes in their nocturnal perches in the typical rest, loose-coiled, head down

TABLE 1. Activity areas and movement characteristics of female *Oxybelis aeneus* in tropical dry forest of Chamela, Jalisco, México.

Individual identification	SVL (mm)	Number of relocations minimum convex polygon(ha)	Activity area — movements (>10 m)	Percentage of significant traveled (m)	Mean distance
Oa I	730	23	2.9	17.39	29.03
Oa II	900	26	1.47	12.5	7.22
Oa III	630	10	0.004	0	1.19
Oa IV	940	22	0.05	9.09	6.2
Oa V	790	21	0.49	14.28	9.69
Oa VI	800	26	0.2	11.53	9.32
Oa VII	860	22	0.05	9.09	6.94

position (Henderson 1974. Herpetologica 30:19–24). These snakes were located 85 and 178 cm above the ground within dense vegetation, which made observation difficult.

During this study there were several opportunities when it was possible to observe the foraging behavior of *O. aeneus*. A total of 20 foraging events was recorded, 17 (85%) towards *Aspidoscelis* spp., 2 (10%) towards *Anolis* spp. and 1 (5%) towards *Plestiodon parvulus*: only 3 (15%) all of these foraging events were successful, two for *Aspidoscelis* and one for *Plestiodon parvulus*. In all the observations the snakes used ambush foraging behaviors and active pursuit of prey was never observed.

Our results suggest that female *O. aeneus* have small, defined activity areas and move short distances; several times snakes were relocated in their previous relocation site. On the other hand, two individuals exhibited relatively larger activity areas (1.4 and 2.9 ha). This may be due to some unusual larger movements in which a snake moved outside of its habitual home range and soon returned. Such movements have been observed in female *Stegonotus cucullatus* which move outside of their habitual home range, apparently to oviposit in nesting sites, and then return to the areas usually occupied (Brown et al. 2005. J. Trop. Ecol. 21:605–612). In our case, however, we did not detect that any of the monitored females were gravid. Restricted movement by female *O. aeneus* during the dry season apparently minimizes wasted energy and may diminish risk of desiccation. In seasonal environments some snakes drastically increase movement patterns and home range during wet seasons, whereas others maintain similar patterns at both times of the year (Brown et al. 2002. J. Trop. Ecol. 18:549–568). It would be important to know if activity patterns of *O. aeneus* during the dry season are maintained during the rainy season.

The movement patterns and behavior that we observed suggest that *O. aeneus* is primarily a sit and wait predator. Similar patterns have been observed in other arboreal colubrids such as *Uromacer catesbyi* and *U. oxyrhynchus*, which spend about 95% of daylight hours relatively motionless, looking for active prey, and only descend to the ground to look for a new ambush site (Lillywhite and Henderson 1993. *In* Seigel and Collins [eds], Snakes: Ecology and Behavior, pp. 1–48. McGraw-Hill, Inc. New York). A similar pattern was also reported in vipers such as the Asian viper *Gloydius shedaoensis*, which is an extremely sedentary hunter. The home range in this species is 0.3 ha with daily movements of less than two meters (Shine et al. 2003. Oikos 2:342–352). Snakes using these foraging strategies have been defined by Greene (1997. Snakes: The Evolution of Mystery in Nature. University of California Press, Berkeley. 317 pp.) as mobile ambushers, that is to say, serpents that remain from days to months in the same site before moving to another place.

We thank Posgrado en Ciencias Biológicas de la UNAM and CONACYT for funding and the personnel and friends of the Estación de Biologia Chamela. Robert Henderson, David Hardy Sr., and Vincent Cobb provided information and valuable literature. Daniel Beck and two anonymous reviewers commented on earlier versions of this note.

***OXYRHOPUS PETOLA DIGITALIS* (False Coral Snake). PREY.** Snakes of the genus *Oxyrhopus* feed on a wide variety of prey, but seem to be primarily predators of lizards and small mammals (e.g., Duellman 1978. Misc. Publ. Mus. Nat. Hist. Univ. Kansas 65:1–352; França et al. 2008. Copeia 2008:23–38; Vitt and Vangilder 1983. Amphibia-Reptilia 4:273–296). On 3 August 2007, at 1935 h, three of us (DV, MAG, CCS) found an adult female *Oxyrhopus petola digitalis* (SVL = 855 mm; tail length = 235 mm; 178 g) at the border of a forest fragment (22.445694°S, 42.764056°W, datum: SAD 69) near the Reserva Ecológica de Guapiaçu (REGUA) in the district of Guapiaçu, municipality of Cachoeiras de Macacu, state of Rio de Janeiro, Brazil. The snake was promptly captured and placed in a cloth bag. The next day, it had regurgitated a rodent (*Oligoryzomys nigripes*; 28.5 g) inside the bag (Fig. 1). The snake is currently housed at the reptile collection of the Museu Nacional, Rio de Janeiro (MNRJ 15370). The skin and skeleton of the rodent were deposited at the mammal collection of the same museum (MN 72716). Previous prey records for *O. p. digitalis* have included small mammals, lizards, and birds (Bernarde and Machado 2000. Herpetol. Rev. 31:247–248; Duellman, *op. cit.*; Palmuti et al. 2009. Biota Neotrop. 9:263–269; Rocha and Vrcibradic 1998. Cienc. Cult. 50:364–368). In most cases, mammalian prey have not been identified to species or genus, with the exception of Rocha and Vrcibradic (*op. cit.*) who provided the identity of the snake's prey as the rodent *Akodon cursor*. The present record adds another case of predation on mammals by *O. p. digitalis* and is the second in which the mammal prey was identified to species.

We thank Lena Geise for identifying the rodent species, IBAMA for issuing collection permit no. 13088-1, and Nicholas J. Locke of the Reserva Ecológica de Guapiaçu (REGUA) for making many facilities available during our fieldwork in that area. Fieldwork was funded by grants from Fundação Biodiversitas and RAN-ICMBio (0158A-012006), from the Conselho Nacional do Desenvolvimento Científico e Tecnológico - CNPq (Processes 307653/03-0 and 476684/2008-8) and from Fundação Carlos Chagas Filho de Amparo à Pesquisa do Estado do Rio de Janeiro – FAPERJ (Process E-26/102.404.2009) to CFDR. MAG and CCS received graduate fellowships from Conservation International do Brasil and CNPq, respectively.

***PANTHEROPHIS BAIRDI* (Baird's Ratsnake). DIET AND FORAGING BEHAVIOR.** A *Pantherophis bairdi* was found inside a cave (La Sepultura) in the municipality of Cd. Victoria, Tamaulipas, México (23.7756667°N, 99.2288056°W, datum WGS84; elev. 597 m). The snake was found coiled 2 m above the ground along one of the walls of the cave attempting to catch bats of the species *Leptonycteris curasoae* (Fig. 1). Other species of bats found and identified in this cave included *Desmodus rotundus, Diphylla ecaudata,* and *Pteronotus parnelli*. Previous reports mention that *P. bairdi* preys on rats, mice, bats, birds, bird eggs, and lizards, without reference to specific species or families of each group (Schulz 1996. A Monograph of the Colubrid Snakes of the Genus *Elaphe* Fitzinger. Koeltz Scientific Books, Czech Republic. 439 pp.). Schulz (1996, *op. cit.*) mentions that caves are inhabited by several species of rat snakes at least temporarily. For example, *Pantherophis guttata, P. obsoleta,* and *Senticolis triaspis* were recorded from caves occupied by bats, which served as prey. Moreover, the only known *P. bairdi* record in this municipality was published in 2009, but referred to a specimen found by T. W. Walker in 1969 (Farr et al. 2009. Herpetol. Rev. 40:459–467). Thus, this record represents the second municipality record in a span of over 40 years. The snake and bats were not caught or collected and were identified photographically and with the help of Luis Canseco-Márquez and Arnulfo Moreno-Valdez, respectively. We also thank David Lazcano-Villarreal for revising the manuscript.

***PANTHEROPHIS SPILOIDES* (Gray Ratsnake). REPRODUCTIVE BEHAVIOR / ARBOREAL MALE COMBAT.** The goal of male combat in snakes is to establish dominance over an opponent through physical superiority (Gillingham 1987. *In* Seigel et al. [eds.], Snakes: Ecology and Evolutionary Biology, pp. 184–209. McGraw-Hill Publishing Co., New York). Male ratsnakes compete for mates by participating in dominance "combat dances" (Rigley 1971. J. Herpetol. 5:65–66; Stickel et al. 1980. Amer. Midl. Nat. 103:1–14); although the role of this behavior is not fully understood (Rigley, *op. cit.*). The arboreal habits of species in the *Pantherophis obsoleta* complex are also well documented (Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Institution Press., Washington, D.C., 681 pp.), and arboreal mating has been noted in *P. o. obsoleta* (Padgett 1987. Catesbeiana 7:27–28), but to our knowledge, arboreal male combat has not been reported.

On 24 May 2006 at 1200 h, we observed a pair of free-ranging male *Pantherophis spiloides* engaged in arboreal combat on the Camp Shelby Joint Forces Training Center, Forrest Co., Mississippi, USA. The snakes were found entwined approximately 5 m above ground, hanging from a broken limb in a *Quercus marilandica* (Fig. 1). The smaller male (SVL = 141 cm, 612 g) continued to break contact and move up the tree, and was followed by

PHOTO BY T. M. DICKINSON

FIG. 1. Two adult male *Pantherophis spiloides* engaged in arboreal combat in Forrest Co., Mississippi, USA.

the larger male (SVL = 148.5 cm, 814 g). The larger male would continuously initiate contact and entwine with the smaller male along the tree branches attempting to press down the smaller male's head. At approximately 1235 h, the two snakes entered a decaying cavity of a limb and were unobservable. At 1239 h, the two snakes emerged from the cavity and began to move, entwined, towards the ground.

At approximately 1245 h, the two snakes reached the ground and continued in combat for 5 minutes until the smaller male retreated into nearby shrubbery without the larger male following. At this time, the snakes were collected for measurements and released at the point of capture the following day. A female *P. spiloides* was never observed to be present during this display or combat ritual. The behavior exhibited by both snakes was similar to the combat sequences described by Gillingham (1980. Herpetologica 36:120–127) for captive snakes.

We thank James R. Lee and Geoffrey G. Sorrell for their comments.

***PITUOPHIS MELANOLEUCUS LODINGI* (Black Pinesnake). REPRODUCTION and NEST LOCATION.** Our knowledge of *Pituophis melanoleucus* nesting ecology is primarily a result of intensive research conducted on a disjunct population of the nominate race, located at the northern limit of the species range (i.e., New Jersey Pine Barrens; Burger and Zappalorti 1986. Copeia 1986:116–121; Burger and Zappalorti 1991. J. Herpetol. 25:152–160). Although the first natural nest of *P. m. melanoleucus* outside of the Pine Barrens has recently been described (Beane and Pusser 2007. Herpetol. Rev. 38:469), information on nesting locations of the two more southerly distributed races remains anecdotal (i.e., *P. m. mugitus*: Franz 2005. *In* Meshaka, Jr. and Babbitt [eds.], Amphibians and Reptiles: Status and Conservation in Florida, pp. 120–131. Krieger Publ. Co., Malabar, Florida; Miller 2008. M.S. thesis, Univ. of Florida), or unknown (i.e., *P. m. lodingi*). In a note on *P. catenifer sayi* nesting, Iverson et al. (2007. Herpetol. Rev. 38:92) stated, "These data suggest that *P. melanoleucus* excavates its nest burrows, whereas *P. catenifer* uses natural cavities or burrows for oviposition; however, further data are needed for both species to determine the universality of this pattern." Herein we report a novel nesting location for *P. melanoleucus*, and provide, to our knowledge, the first published description of a natural nest of *P. m. lodingi*. The following observation took place in the southwestern portion of the Camp Shelby Joint Forces Training Center, Perry Co., Mississippi, USA.

On 3 September 2009, while searching the area around the last known location (i.e., burrow) of a telemetered *Gopherus polyphemus* (Gopher Tortoise), whose radio transmitter prematurely failed a month earlier, one of us (MGH) captured two hatchling *P. m. lodingi* which were basking on, or adjacent to, the apron of the tortoise burrow. On 4 September 2009, we revisited the site to excavate the burrow and immediately found a third hatchling *P. m. lodingi* tightly coiled and basking in the open, 6 m from the burrow's entrance. After taking some basic burrow measurements (i.e., width = 6.4 cm, height = 3.5 cm, angle of declination from the soil surface = 27°) following the methods of Doonan and Stout (1994. Am. Midl. Nat. 131:273–280), we excavated the burrow and located a clutch of six recently hatched eggs (cemented together in a single cluster) and two hatchling sheds at the burrows terminus (74 cm below the soil surface; measured to the bottom of the nest chamber). The straight line distance from the burrow's entrance to the terminus measured 161.9 cm; however, the total length of the burrow including turns (Doonan and Stout 1994, *op. cit.*) measured 188 cm. The chamber at the end of the burrow had a width of 14.5 cm and a height of 9 cm. The entire chamber and the last ~1/3 of the burrow were loosely packed with soil; however, a small tunnel (1.5 cm in diameter) extending from the chamber, presumably the route made by the exiting hatchling snakes, was observed. The tortoise was not found during the excavation, but was discovered 13 d later on the apron of a burrow that it had constructed previously.

The nest/burrow was located in a sandy area (McLaurin-Bendale soil series), with an open *Pinus palusrtis* (Longleaf Pine) canopy (canopy closure = 8%; estimated with a convex spherical crown densiometer), sparse mid-story (10%; visual estimate within 10 m^2), moderate *Andropogon* sp. (bluestem) dominated understory (60%; visual estimate within 10 m^2), and was in close proximity to a road (45 m); which are similar habitat characteristics reported for *P. m. melanoleucus* nests elsewhere (Burger and Zappalorti 1986, *op. cit.*; Burger and Zappalorti 1991, *op. cit.*; Beane and Pusser 2007, *op. cit.*). Interestingly, the depth of the nest reported here (74 cm), is nearly twice as deep as the nest found in North Carolina (41 cm; Beane and Pusser 2007, *op. cit.*), and three times deeper than those found in New Jersey (≤ 25 cm; N = 93; Burger and Zappalorti 1991, *op. cit.*). Although researchers have noted that *P. m. lodingi* infrequently utilize tortoise burrows as retreat sites (Baxley and Qualls 2009. J. Herpetol. 43:284–293; J. Lee, unpubl. data), this microhabitat likely plays an important role in the reproductive ecology of the Black Pinesnake, and may provide a suitable microclimate for the incubation of *Pituophis* eggs in warm climate areas (e.g., the southeastern portion of the species range).

We thank the Mississippi Army National Guard and the U.S. Forest Service for allowing us to conduct research on their properties, and M. Lyman and A. Schneider for assisting with burrow excavation. All work was conducted in accordance with Mississippi Department of Wildlife, Fisheries, and Parks Administrative Scientific Collecting Permit Number 0502091.

JAMES R. LEE (e-mail: jlee@tnc.org), **DONALD J. NEWMAN III**, and **MATTHEW G. HINDERLITER**, The Nature Conservancy, Camp Shelby Joint Forces Training Center, CSJFTC-ENV Building 622, Camp Shelby, Mississippi 39407, USA.

***PITUOPHIS MELANOLEUCUS MUGITIS* (Florida Pinesnake). PREDATION.** On 22 June 2007, at ca. 1130 h, one of us (TWT) observed a *Pituophis melanoleucus* (ca. 1.2 m total length) crossing a dirt road bisecting a tract of mature Longleaf Pine (*Pinus palustris*) forest on the Joseph W. Jones Ecological Research Center at Ichauway Plantation, Baker Co., Georgia, USA (31.210946°N, 84.445900°W; datum WGS84). The snake moved from the road into a briar thicket. Approximately 90 min later a bird-of-prey believed to be either a *Buteo jamaicensis* (Red-tailed Hawk) or *B. lineatus* (Red-shouldered Hawk) was startled from the brush and was seen carrying what appeared to be a dead *P. melanoleucus* (ca. 1.2 m total length) in its talons as it crossed the road approximately 50 m west of where the snake was sighted previously. Both

Red-shouldered and Red-tailed Hawks are present on Ichauway and are known to include snakes in their diet (Crocoll 1994. *In* A. Poole [ed.], The Birds of North America Online. Cornell Laboratory of Ornithology, New York; Preston and Beane 1993. *In* A. Poole and F. Gill [eds.], The Birds of North America.The American Ornithologists' Union, Washington, DC). Although Red-tailed Hawks prey heavily on *P. catenifer* (Gophersnake) in the western United States (Fitch et al. 1946. Condor 48:205–237; Grothe 1992. Red-tailed Hawk Predation on Snakes: The Effects of Weather and Snake Activity. M.S. thesis. Idaho State University. 103 pp.), birds of prey are not listed among predators of *P. melanoleucus* (Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Books, Washington D.C. 668 pp.; Gibbons and Dorcas 2005. Snakes of the Southeast. Univ. Georgia Press, Athens. 253 pp.). To the best of our knowledge, this observation represents the first documentation of *P. melanoleucus* being depredated by a hawk.

MATTHEW P. GREENE, 30496 280th Street, Shell Rock, Iowa 50670, USA (e-mail: oldgrowthlongleaf@gmail.com); **THOMAS W. TRACY**, F&W Forestry Services, Inc., PO Box 3610, Albany, Georgia 31706, USA.

***PSOMOPHIS JOBERTI* (NCN). REPRODUCTION.** *Psomophis joberti* is a small species distributed in Brazil, Paraguay, and Bolivia. Despite its wide geographic distribution in South America, information on the ecology of this secretive species is limited to anecdotal reports on diet (Strüssman and Sazima 1993. Stud. Neotrop. Fauna Environ. 28:157–168) and behavior (Lima et al. 2010. Herpetol. Rev. 41:96–97). Herein, we present information on clutch size and reproductive investment for this species.

On 13 November 2009, we collected an adult female *P. joberti* (SVL = 388 mm; 11.0 g after egg removal) road-killed near Pentecoste Municipality, Ceará, Brazil (3.82145°S, 39.33824°W, datum: WGS84). Upon dissection, we found seven oviductal eggs (largest egg length = 14.2 mm; total eggs mass = 6.2 g). The relative clutch mass (total clutch mass / female mass without eggs) was high (approximately 0.56) representing an exceptionally high reproductive investment, especially considering that the eggs were not fully developed. To our knowledge, this is the first report on reproduction and clutch size for *P. joberti*. The snake is deposited in the herpetological collection of Universidade Federal do Ceará (CHUFC 3421).

PAULO CESAR MATTOS DOURADO DE MESQUITA (e-mail: pauloc-mdm@gmail.com), **WALLONY BRITO** (e-mail: wallony.brito@hotmail.com), and **DIVA MARIA BORGES-NOJOSA** (e-mail: dmbnojosa@yahoo.com.br), Núcleo Regional de Ofiologia of the Universidade Federal do Ceará (NUROF-UFC), Campus do Pici, Depto. Biologia, Bl. 905, CEP 60.455-760, Fortaleza, CE - Brazil.

***PYTHON MOLURUS BIVITTATUS* (Burmese Python). REPRODUCING POPULATION.** The population of introduced *P. m. bivittatus* in Everglades National Park (ENP), Florida, USA is growing rapidly (Snow et al. 2007. *In* Henderson and Powell [eds.], Biology of the Boas and Pythons, pp. 416–438. Eagle Mountain Publishing, Utah). This growth has raised concerns about geographic expansion and the establishment of new populations. In areas of southern Florida outside of the core of the introduced range, large individuals are increasingly being noted in the popular news media. However, smaller individuals seem to be encountered much less frequently in the invasion periphery. Because the probability is arguably low that very young pythons found in wild areas are released/escaped from captivity, any such observations would suggest that reproduction was taking place at those locations.

At 0420 h local time on 26 July 2009, I discovered a male hatchling *P. m. bivittatus* (total length = 599 mm; tail length = 90 mm; 122 g, conspicuous umbilical scar, no gastric or cloacal contents externally palpable) dead on the road surface of Tamiami Trail (U.S. Highway 41) in Collier Co., Florida, USA. At this location (25.98723°N, 81.57438°W, datum: WGS84), the road is within the boundaries of Collier-Seminole State Park (CSSP). The snake had been hit once on the head while crossing from north to south. Based on the low level of traffic at that hour, I estimate it was killed no more than 1 h earlier. The roadside vegetation included palms, dense shrubs, and grasses. The habitat to the south was estuarine tidal marsh. A small brackish canal with mangroves runs along the north side of the road. Beyond the canal was freshwater marl prairie, with wet flatwoods 200 m further north. With regard to possible egg incubation sites, the nearest microhabitats not permanently or seasonally inundated were the road embankment itself, and a patch of scrubby flatwoods about 500 m to the NW. Night drives through this area over the following three nights yielded no additional specimens. The whole specimen, a tissue sample, and a photo voucher (image provided by R. W. Snow) are deposited in the Florida Museum of Natural History (UF 155674; species identity verified by K. E. Krysko).

This record represents the first direct evidence of *P. m. bivittatus* reproduction in Collier Co., Florida; previous Florida records of reproductive females, eggs, or hatchlings are from either Miami-Dade or Monroe counties (Snow et al. 2007. Herpetol Rev 38:93; Brien et al. 2007. Herpetol Rev 38:342–343; Krysko et al. 2008. Applied Herpetol. 5:93–95). If, as seems likely, this snake hatched in the wild, there are at least three possible interpretations of the population status of *P. m. bivittatus* in Collier Co.: 1) this record represents the first instance of successful reproduction; 2) reproduction is irregular (e.g., only in years with particular weather conditions), only in scattered locations, or occurs at very low frequency; or 3) reproduction is occurring frequently, but small pythons have an extremely low detectability. Interpretation 1 is unlikely, but cannot be discounted; if this is indeed the first instance, then land managers may start encountering juvenile pythons in Collier Co. As for interpretation 2, I independently queried two staff members at CSSP in 2008 about python sightings in that park; both agreed that between six and ten large (> 2.5 m total length) pythons had been seen in CSSP in the preceding 5–6 years, but no smaller pythons had been found. Even if the previous apparent absence of hatchlings was attributable to lack of road surveys, the lack of larger juveniles (1.0–2.4 m) suggests that pythons have not been regularly reproducing in CSSP heretofore. Regarding interpretation 3, *P. m. bivittatus* hatchlings are the same size as many native snakes. In 11 nights of driving the roads (1995 miles, 55.5 h) of Collier Co. from 02–09 August 2008 and 21–29 July 2009, I encountered the single hatchling python and at least 59 native snakes on the road. For comparison, I was systematically roadcruising in ENP during these same two time periods and observed five hatchling pythons and 102 native snakes in six nights of driving (1820 miles, 49.5 h). These comparative observations suggest that small pythons on roads are detectable, and further, indicate that the frequency of reproduction in Collier Co. is much lower than in ENP. Although future

work is needed to determine factors that influence detectability of hatchling pythons, systematic road cruising on summer nights might be a useful method for assessing the reproductive status of *P. m. bivittatus* populations.

I thank M. Patel and J. Innis for sharing their observations, K. Wilson and the entire staff at CSSP for many kindnesses and field assistance, S. Snow for sharing observations, insights, and suggestions, T. Hingtgen for facilitating permits, R. Reed for advice, contacts, and support, D. W. Pearson for information, T. and M. Walters for lodging, and A. Flanagan for his python expertise and roadcruising camaraderie. The specimen was salvaged under permit from the Florida Department of Environmental Protection.

PAUL T. ANDREADIS, Department of Biology, Denison University, Granville, Ohio 43023, USA; e-mail: nerodia@denison.edu.

***PYTHON SEBAE* (Northern African Python or African Rock Python). SIZE.** *Python sebae* is the largest snake in Africa, and one of the largest in the world. As with most giant snakes, *P. sebae* exhibits female-biased sexual size dimorphism. Although there are numerous claims about overall maximum size for this species (Murphy and Henderson 1997. Tales of Giant Snakes. Krieger Publ. Co., Malabar, Florida. 221 pp.), the largest individuals are likely females. Literature reviews suggest males attain maximum sizes of about 4 m total length and 30–40 kg (Reed and Rodda 2009. Giant Constrictors: Biological and Management Profiles and an Establishment Risk Assessment for Nine Large Species of Pythons, Anacondas, and the Boa Constrictor. U.S. Geological Survey Open-File Report 2009-1202, and references therein). Herein, we report on the largest known male *P. sebae* from an introduced population in Florida, possibly representing a new male size record for the entire species.

In response to a series of observations of *Python sebae* in the Bird Drive Basin area of western Miami (Miami-Dade Co., Florida, USA; Reed et al. 2010. IRCF Reptiles and Amphibians 17:52–54), an organized search for pythons was conducted during 12–14 January 2010; coincidentally, the search occurred just after a record prolonged cold snap in southern Florida during the first 11 days of January 2010. On 12 January 2010 at 1428 h (approx. 15°C ambient air temperature, with NNW winds at 15 kph), a male python was captured on a canal bank (25.7551°N, 80.4708°W, datum WGS84) by J. Dozier, D. Hazelton, and J. Prieto. The python was sluggish after a night during which temperatures in Miami dropped to 4.9°C, but later became active enough to partially escape from a bag that was not sufficient to fully contain it. The python exhibited no evidence of respiratory infection or other illness during initial examination, and was then euthanized. Body size was as follows: total length = 440 cm, SVL = 405 cm, maximal girth = 59 cm, 62.96 kg. The python was male, confirmed by voluntary eversion of hemipenes during capture, enlarged pelvic spurs, and observation of testes during necropsy. The skeleton, skin, and tissues from this specimen were accessioned into the Florida Museum of Natural History (UF 157217). Another large (total length = 376 cm, SVL = 336 cm, 32.9 kg) male was captured nearby during 12–14 January 2010, as were three adult females (total lengths 297–400 cm).

The larger male *Python sebae* is notable not only for its length, but also for its mass; despite being captured during winter when feeding is likely uncommon, the python was in excellent body condition (9.25 kg of fat bodies were recovered from the carcass), as were most of the four other pythons. Although larger individual *P. sebae* are known from the native range, most are confirmed or suspected to be female. Observations in Florida lend support to the proposal that sexual size dimorphism might be reduced in *P. sebae* as compared to *P. molurus* and other giant constrictors (Reed and Rodda 2009, *op. cit.*).

We thank G. Alexander, D. Broadley, R. Drewes, and L. Luiselli for input on body size of *P. sebae*.

***RINECHIS SCALARIS* (Ladder Snake). MAXIMUM SIZE.** *Rinechis scalaris* is a large colubrid that inhabits most of the Iberian Peninsula, southeastern France, and areas of northwestern Italy (Arnold and Ovenden 2002. Field Guide to the Reptiles and Amphibians of Britain and Europe. Collins, London. 288 pp.). The maximum size previously recorded for the species was a 1570 mm total length (TL) female (Cheylan and Guillaume 1993. *In* Böhme [ed.], Handbuch der Reptilien und Amphibien Europas. Band 3/I: Schlangen [Serpentes] I [Typhlopidae, Boidae, Colubridae 1: Colubrinae], pp. 397–429. Aula-Verlag, Wiesbaden). However, that record was from an insular population that is known to contain an unusually high proportion of large individuals, reflecting a lack of large predators. In southwestern Spain, maximum SVL recorded was 1385 mm, with a mean tail length of 15.5% (Pleguezuelos 2006. *In* Carrascal and Salvador [eds.], Enciclopedia Virtual de los Vertebrados Españoles. Museo Nacional de Ciencias Naturales. Madrid). Generally, specimens greater than 1200 mm TL are rare (Arnold and Ovenden, *op. cit.*) and sexual size dimorphism has not been reported (Pleguezuelos, *op. cit.*).

On 20 September 2007, a male *R. scalaris* was received at the Centro de Rescate de Anfibios y Reptiles (Alcalá la Real, Spain). Measurements were: TL = 1650 mm (tail slightly incomplete); SVL = 1410 mm (measured using ImageJ images analysis software). The specimen was found in a building site on the outskirts of a medium-size village (37.46°N, 3.93°W, datum: ED50; elev. 1000 m), surrounded both by forest and agricultural landscape. High densities of large prey favored by male *R. scalaris* (e.g., *Rattus* sp.) can be found in this habitat (Palomo and Gisbert 2002. Atlas de los Mamíferos Terrestres de España. Dirección General de Conservación de la Naturaleza-SECEM-SECEMU, Madrid. 564 pp.), even though this species seldom uses urban areas (Pleguezuelos, *op. cit.*).

***SALVADORA HEXALEPIS DESERTICOLA* (Big Bend Patch-nosed Snake). DIET AND PREDATION.** Witnessing tritrophic interactions among vertebrates is rare. One mechanism for such an event is that a predator is vulnerable while ingesting a prey item, presenting an opportunity for a second predator. Because snakes must swallow prey whole, they are especially vulnerable to predation while subduing and ingesting prey. For example, anacondas are vulnerable to predators during and after ingesting prey and often tighten their hold on prey when approached while feeding (Murphy and Henderson 1997. Tales of Giant Snakes: A Historical Natural History of Anacondas and Pythons. Krieger Publ. Co., Malabar, Florida. 221 pp.). Here we report a tritrophic interaction involving a *Geococcyx californianus* (Greater Roadrunner), a *Salvadora hexalepis deserticola*, and an *Aspidoscelis tesselata* (Common Checkered Whiptail).

Lizards are the primary prey of *Salvadora*, but few dietary data exist. Painter (1985. Herpetology of the Gila and San Francisco River Drainages of Southwestern New Mexico. Unpubl. report, New Mexico Game and Fish, Santa Fe. 333 pp.) and Degenhardt et al. (1996. Amphibians and Reptiles of New Mexico. Univ. New Mexico Press, Albuquerque, New Mexico, 431 pp.) reported that *S. h. deserticola* feeds on lizards, reptile eggs, small mammals, and grasshoppers. Greater Roadrunners are known to prey on snakes such as *Micruroides euryxanthus, Crotalus atrox*, and *Pituophis catenifer* (Sherbrooke and Westphal 2006. Southwest. Nat. 51:41–47). To our knowledge, this is the first report of *S. hexalepis* preying on *A. tesselata*, and the first report of a Greater Roadrunner preying on *S. hexalepis*.

On 3 May 2009 at ca. 0930 h, we were driving along Aguirre Springs Road in the Organ Mountains, Doña Ana Co., New Mexico, USA (32.411924°N, 106.547928°W, datum: WGS84; elev. 1524 m) when we observed a Greater Roadrunner that had captured a *S. h. deserticola*. The roadrunner was startled by our vehicles, dropped the snake on the road, and ran away before it could be photographed. The abandoned snake appeared uninjured and had an adult *A. tesselata* in its mouth. The snake was gripping the whiptail laterally by the torso and immediately dropped the lizard when we picked it up. Although neither predatory attack was observed, we presume that the roadrunner attacked the snake after the snake had captured the lizard. The released *A. tesselata* was sluggish, did not attempt to escape from our hands when picked up, and died within 5 min. Although its behavior suggested injury, there were no visible puncture wounds, but a small amount of blood was present on the torso; thus, we were unable to ascertain if the blood came from the lizard or the snake. Prey is seized and chewed by *S. h. deserticola* (Ernst and Ernst 2003. Snakes of the United States and Canada. Smithsonian Institution Press, Washington, D.C. 680 pp.).

This event occurred during an educational field trip sponsored by the National Science Foundation GK-12 Ecohydrology of the Middle Rio Grande Environment (E-MRGE) fellowship program at the University of New Mexico. Eight 7th grade students from Belen Middle School witnessed this real-life example of complex foodweb interactions in a desert ecosystem. We thank GK-12 fellows J. Snider and T. Salem and PIs S. Collins and L. Crossey for encouraging the development of the Belen Outdoor Education Program. We thank M. Ryan for his valuable comments on the manuscript and I. Latella for providing relevant literature resources.

***SINONATRIX PERCARINATA SURIKI* (White-bellied Watersnake). DIET.** In Taiwan, *Sinonatrix percarinata suriki* primarily preys on frogs (e.g., *Fejervarya limnocharis* and *Rana longicrus*), and fishes (e.g., *Channa asiatic*, *Misgurnus anguillicaudatus*; Mao 2003. Population Ecology of Genus *Sinonatrix* in Taiwan. Doctoral dissertation, Trier University, Germany. 157 pp.). At 2245 h on 1 September 2007, during a routine survey of a *S. p. suriki* population in a hydrophytic pond of Fushan Botanical Garden, Ilan County, northern Taiwan (24.75975°N, 121.58367°E, datum: TWD97; elev. 665 m), a female *S. p. suriki* (total length = 489 mm; tail length = 115 mm) was observed moving among the leaves of a Taiwanese Yellow Pond Lily (*Nuphar shimadai*). The snake had an obviously enlarged mid-body and was forced to regurgitate a partially digested *Babina adenopleura* (Olive Frog; SVL = 47 mm; 6.6 g), which had been ingested vent-first. The snake was then released at its capture location.

Babina adenopleura is a fairly common anuran in mountainous wetlands (e.g., lakes, ponds, and pools) of northeast Taiwan from 300–2000 m elevation. Its tadpoles are the largest of the 31 native anuran species of Taiwan and have been observed to coexist with some *S. p. suriki* populations in Ilan County. Previously, a male *S. p. suriki* was observed preying on a tadpole of *B. adenopleura* in Mystries Lake, Ilan County, Tiawan (Mao, unpubl. data). However, to our knowledge, this is the first published report of *S. p. suriki* utilizing the adult frogs or tadpoles of *B. adenopleura* as food resources.

***TAENIOPHALLUS AFFINIS* (NCN). DEFENSIVE BEHAVIOR.** *Taeniophallus affinis* is a snake in the family Dipsadidae that is found in leaf litter in forested areas of southeastern and southern Brazil. Studies of the natural history of this species are lacking, and its defensive behavior is poorly documented. There are several defensive tactics used by snakes (Greene 1988. *In* Gans and Huey [eds.], Biology of the Reptilia, 16, pp. 1–152. Alan R. Liss, New York), and eversion of hemipenes has been observed in many species. Sazima and Abe (1991. Stud. Neotr. Fauna Environ. 26:159–164) observed this tactic in *Micrurus frontalis* from Minas Gerais, Brazil, and Martins (1996. *In* K. Del Claro [ed.], Anais XIV Encontro Anual de Etologia, pp. 185–199. Sociedade Brasileira de Etologia, Uberlândia, Brazil) reported it in *Erythrolamprus aesculapii* and *Imantodes cenchoa* from the Central Amazon. We observed an everted hemipenis in a specimen of *T. affinis* (SVL = 502 mm; tail length = 141 mm; 48.0 g) collected from a pitfall trap in the Parque Natural Municipal de Sertão (28.0456°S, 52.2141°W, datum: WGS84; elev. 670 m), Rio Grande do Sul, Brazil. The individual everted its hemipenis after being manipulated for photographs. This specimen was deposited in the Coleção de Répteis da Universidade de Passo Fundo (CRUPF 1698).

***THAMNOPHIS CYRTOPSIS* (Black-necked Gartersnake). REPRODUCTION / AUTUMN COURTSHIP.** Male *Thamnophis cyrtopsis* are thought to follow a postnuptial pattern of reproduction, with males reaching maximum testicular weight and peak rate of spermiogenesis in autumn, prior to winter brumation (Goldberg 1998. Texas J. Sci. 50:229–234). However, females enter winter brumation with small, previtellogenic follicles and undergo secondary vitellogenesis and ovulation in spring, following emergence (Goldberg 1998, *op. cit.*). It is assumed that most breeding takes place in spring, but based on the male spermiogenic cycle in Arizona there is a possibility that some autumn breeding may occur (Goldberg 1998, *op. cit.*). The purpose of this note is to report an instance of courtship and suspected autumn copulation in *T. cyrtopsis*.

At Chimenea Canyon, Saguaro National Park (Pima Co., Arizona, USA; 32.15285°N, 110.60906°W; datum: NAD83; elev. 1033 m) on 19 November 2005, at 1124 h, one of us (EWS) encountered a pair of adult *T. cyrtopsis* engaged in courtship (Fig. 1). Both snakes were of similar size, estimated to be between 55–70 cm total length. The snakes were loosely intertwined in a circle on a substrate of coarse sand and leaf litter, ca. 2 m from a small (1 m^2), shallow (< 30 cm) pool in partial shade. One snake's tail was held to the side, with the other's wrapped alongside and around it in classic copulatory posture. The anterior 75% of each snake's body was still, while the posterior of one snake's tail made several quivering motions over 5–10 sec., leading us to suspect that copulation was occurring. However, no postcloaca bulge was observed so we cannot conclude that intromission occurred. The snakes were aware of the observer's presence, who watched for 8–10 min. When an attempt was made to capture the snakes for measuring and to confirm sex, they quickly escaped under a large boulder < 0.5 m away. The shaded ambient temperature was 22.5°C, substrate temperature was 27.0°C, and overnight low temperature the previous night was ca. 10°C.

Our observation appears to be the first evidence that *T. cyrtopsis* in southeastern Arizona engages in courtship behaviors in the fall, which may place it among *T. atratus*, *T. ordinoides*, and *T. sirtalis* for which autumn breeding has been reported (Rossman et al. 1996. The Garter Snakes: Evolution and Ecology. Univ. Oklahoma Press, Norman. 332 pp.).

FIG 1. Two *Thamnophis cyrtopsis* engaged in suspected copulation at Saguaro National Park, Arizona, USA, on 19 November 2005.

We thank Steven Goldberg for providing constructive comments on the manuscript.

***THAMNOPHIS SIRTALIS PARIETALIS* (Red-sided Gartersnake). GIGANTIC SIZE.** *Thamnophis sirtalis parietalis* is a wide-ranging snake that provides a good model for understanding how growth rates and biological variables are expressed in reptiles across a range of geographic conditions (Aleksiuk and Stewart 1971. Ecology 52:485–490; O'Donnell et al. 2004. Behav. Ecol. Sociobiol. 56:413–419). Here we describe the presence of gigantic *T. s. parietalis* at the northern limit of their range in Manitoba, Canada. Of the 514 snakes captured between April 2005 and October 2006 near Jenpeg, Manitoba (54.3321°N, 98.3161°W; datum WGS 84), three individuals exceeded the previous length record of 1241 mm (Conant and Collins 1998. A Field Guide to Reptiles and Amphibians of Eastern and Central North America, 3rd ed. Houghton Mifflin Co., Boston, Massachusetts. 616 pp.). The length of the longest individual was 1340 mm total length (SVL = 1060 mm, 435 g). To determine the approximate age of one large female (total length = 1275 mm, SVL = 1020 mm), a tail tip was analyzed using skeletochronology (Waye and Gregory 1998. Can J. Zool. 76:288–294). Although the analysis was not conclusive, it appeared that this individual was approximately 11 ± 1 years old.

Recent research on latitudinal body size variation in snakes has pointed to a number of factors that might influence growth rates and total length (Olalla-Tárragal et al. 2006. J. Biogeog. 33:781–793). Although latitudinal body size trends in snakes are still poorly understood, hibernation survival has been implicated as a strong selective pressure driving gigantism in northern snakes (Ashton 2001. Evolution 52:2523–2533). Snakes that can attain larger sizes have a higher likelihood of surviving the extended periods of hibernation required in northern Manitoba (Gregory 1982. *In* Gans and Pough [eds.], Biology of Reptilia, Vol. 13, pp. 53–154. Academic Press, New York).

***XENODON HISTRICUS* (Rayed or Jan's Hog-nosed Snake). REPRODUCTION.** On 3 November 1962, R. Praderi collected a female *Xenodon histricus* (MNHN 1044; SVL = 310 mm; tail length = 40 mm) at Estancia de Patrón, near Salto Penitente, Dpto. Lavalleja, Uruguay (34.3333°S, 55.1166°W, datum Yacare). We found five eggs in the left oviduct. Mean egg length was 10.17 mm (range: 9.58–11.82 mm). These are the first reproductive data for *X. histricus*, which is seldom encountered throughout its range. The collection date suggests that this species has similar reproductive phenology as other reptile species in the region.

e-mail: reedr@usgs.gov

Invasive species are increasingly recognized as one of the leading threats to global biodiversity. The field has grown complex enough to deserve its own journal (*Biological Invasions*) and encyclopedia (Simberloff and Rejmánek 2011), but the lion's share of attention has been paid to a few groups of organisms, such as rodents, plants, and ballast-water contaminants. While a few species of introduced reptiles and amphibians and certain geographic areas (Florida, Hawaii) have received research attention, most herp introductions have been largely ignored by the herpetological community. Instead, available knowledge of the great majority of herp introductions is scattered throughout a vast body of literature, often as short notes or as minor addenda to papers on tangentially related topics. In this volume, Fred Kraus offers the definitive literature-based treatment of the subject. Lever (2003) was the first to attempt a summary of herpetofaunal introductions, but Kraus goes far beyond Lever on both conceptual and taxonomic grounds, while correcting a number of errors in Lever's summary. For those desiring a general overview of his conclusions but not willing to suffer through this review, Kraus (2010) is brief and accessible.

A prodigious amount of data is shoehorned into the book, and is summarized with prose that is clear and readable. In fact, my overall impression is that this is a great book to read if one has a perverse desire to feel that, comparatively speaking, one's own scholarship is mediocre. I will present relevant statistics first, because an understanding of the volume of literature-based support behind the text will be an important factor for those deciding whether to purchase the book. The five written chapters sum to only 131 pages, but as noted below these five chapters are meaty and deserving of careful reading—they are also profusely illustrated with pertinent figures and graphs (Chapter 2, Introduction Patterns, alone includes 36 figures). These chapters are followed by two appendices of herpetofaunal introductions, with records dating back to 1850. If there's a bigger table than Kraus' Database of Introduction Records (Table A.1) in the herpetological literature, I'd like to see it—the table spans 220 pages. It is followed by a shorter table of erroneous and uncertain introduction claims. The Literature Cited is also massive, covering 167 pages despite a small font size. The sheer size of the tables would make data extraction by the reader a plodding exercise were not an accompanying CD included with the volume, containing a MS Excel file version of the database of 5,745 introductions. The file can be sorted, allowing readers to quickly extract data corresponding to their taxonomic or geographic interests.

Editorial oversight of the book was very good; I noticed only a few minor errors (e.g., p. 3, l. 22, 'than' should be 'that'; p. 60, l. 26, 'on' should be 'of', p. 87, l. 17, 'It's' should be 'Its', p. 32, Table 2.2, 'Teidae' should be 'Teiidae'). The binding has held up to repeated consultations of the text and tables over the last few months, although I did not subject it to the more rigorous Crombie Binding Test (Crombie 1992). I found an important indexing error on p. 557 of the Geographic Index—no entries past p. 217 of the text are indexed for the state of Florida, despite the fact that >80% of the entries for that state are found past this page. Spot-checks for other geographic areas did not reveal this error to be systemic, and the ability to sort the electronic database on the CD should obviate this issue.

Chapter 1 (*Background to invasive reptiles and amphibians*) is a concise introduction to invasive species concepts, including the gamut of processes from transportation and establishment through spread and impacts, as well as a concise history of research on invasive herps. This chapter would serve admirably as part of the introductory readings

for a course on invasion biology, regardless of the conceptual or taxonomic interest of the reader. By page 5, Kraus has already considered and dispensed with the notions that invasive species are beneficial because they increase biodiversity, and that human-caused movement of animals is a 'natural' process. I found Kraus' argument that loss of beauty is an underappreciated but vital aspect of exotic species introductions to be the most riveting part of the chapter. Policy-makers often stress economic or ecological impacts; while Kraus discusses these in depth, he also offers the following: "I suggest that the distinctive co-evolved, unique beauty of (natural ecological) systems is besmirched by the introduction of alien species—much as a beautiful beach or coastline may be impaired by an oil spill. Or perhaps more aptly, the facile pollution of these self-generated biotas by human introductions is equivalent to splattering the canvases in the Louvre with day-glo paint; the structural integrity of the canvases may not be marred, the added colors may be beautiful, but the aesthetic integrity of the artworks is thoroughly violated. The difference, of course is that the impact of an oil spill lasts for mere years, vandalization of a painting may be rectified by careful restoration, but alien invasions are most usually irreversible and irreparable."

Chapter 2 presents introduction patterns for herps. Before 1950, introductions were largely intentional and associated with food and biocontrol pathways, but in later decades the primary pathway switched to the pet trade and the rate of introductions increased exponentially. Kraus calculated this exponential equation and concluded that the number of introductions via the pet trade pathway has been doubling every 15.3 years for the last 10 decades. In terms of established species, the pet trade again leads the way, but release pathways including cargo, intentional releases, the nursery trade, human food source, and biocontrol have been important contributors to the sum total. It is unsurprising that Europe and North America have been the recipients of the most introductions since these regions are the primary consumers of wildlife as pets, but some readers will be discomfited by the U.S. contribution to introductions elsewhere—for example, Kraus reports >1400 records of Red-eared Slider (*Trachemys scripta*) introductions worldwide. Kraus considers the pet trade pathway as intentional introductions, because, "…the importation was intentional and because the consequence of irresponsible ownership of animals will be the frequent and predictable escape of the deliberately imported pets." Researchers do not escape scot-free in this analysis; Kraus presents multiple examples of intentional introductions for scientific purposes, with varying levels of justification for conducting the release. This pathway is important for some taxa, as nearly 40% of all salamander releases were deliberate in nature and associated with research (and >80% of these releases were done by a single researcher!).

While Kraus does a good job of discussing regional (availability of knowledgeable reporters) and climatic (e.g., rates of establishment are lower in Europe than in the U.S.) contributions to reporting bias in herp introductions in Chapter 2, I would have preferred a more direct discussion of taxonomic and perceptual biases. Large (e.g., pythons, crocodilians) or otherwise distinctive (e.g., chameleons) species are much more likely to be noticed and reported than are small, drab, or highly secretive species. This undoubtedly leads to biased interpretations of establishment success—because introductions of small species are less frequently observed, their perceived rate of establishment (no. established populations/ no. introductions) is often high, but in reality the disparity in establishment success between obvious and less-obvious taxa may not be particularly striking. Failure to recognize the potential of taxonomic bias can have policy implications: representatives of the pet trade have used Kraus' calculation of low establishment success for the families Boidae and Pythonidae (they rank second to last and last, respectively, in his tabulation across herpetofaunal families) as 'proof' that large-bodied snakes represent low risk as invaders and therefore that regulatory efforts to reduce the odds of establishment are unnecessary.

Chapter 3 reviews impacts of introduced herps. Some authors have stated that herps tend to pose little threat as introduced species, which has tended to dampen researcher interest in documenting impacts that are assumed *a priori* to be minimal. Based on the few studies that have specifically examined deleterious impacts of introduced herps, Kraus reports that impacts have actually been recorded for a wide range of species. In Florida, for example, negative impacts of introduced herps have been demonstrated for virtually every species that has received research attention, although admittedly this conclusion is influenced by the fact that species that first receive research attention tend to be those that are most feared to have negative impacts. Looking farther abroad, most ecologists are familiar with the avifaunal devastation wrought by the Brown Treesnake (*Boiga irregularis*) on Guam, but may not be aware that, for example, Green Anoles (*Anolis carolinensis*) have caused the decline or extirpation of large numbers of insect species on Japanese islands or that Bullfrogs (*Lithobates catesbeiana*) have been implicated in the decline of a variety of vertebrate taxa at sites all over the globe. These are examples found under only one header (Removal of Native Prey Species) in the chapter; Kraus subsequently reviews ecological impacts including loss of native predators, changes in ecosystem dynamics, competition with natives, vectoring novel pathogens (e.g., chytridiomycosis), and community homogenization. He also examines evolutionary and social impacts, including scientific loss of knowledge based on confusion about native ranges, evolutionary status, or ecological relationships. Kraus ends by saying that 26 herp species can be credibly implicated in impacts

on native wildlife or humans, but that such a relatively low number can likely be ascribed to inattention to impacts and the difficulty of demonstrating such impacts.

It is telling that Chapter 4 (*Management Responses*) is the shortest chapter in the book, as delays in recognizing the potential impacts and scale of herp introductions has curtailed interest in developing such responses among stakeholders, and availability of funding for such endeavors remains anemic as compared to better-known invaders such as mammals, plants, and ballast-water contaminants. Kraus reviews the three legs of the management tripod for exotic species—prevention, early detection, and rapid response, and management of well-established pests. In most countries, prevention of new introductions via regulatory or incentivized means is uncommon, and typically reactive rather than proactive; in other words, importation or ownership bans are enacted only after a species proves pestiferous, thus closing the barn door after the horses have fled. This tendency to consider only some members of taxonomic groups for regulatory action allows the live-animal industry to make compensatory switches after taxon-specific bans, such as was seen when turtle exporters in the United States switched from Red-eared Sliders to Painted Turtles (*Chrysemys picta*) after importation of sliders was prohibited by the European Union (ironically, the painted turtle has a climate match with larger portions of the E.U. than does the slider).

Kraus summarizes the few successes in eradicating invasive amphibians at a local scale (usually single ponds or drainages), but he could find no examples of a successful eradication of an established reptile population anywhere in the world. While Chapter 4 gives the specific details to back up this depressing statistic, the issue is most lyrically summarized in Chapter 1: "A second generality of extremely practical importance is that alien-species naturalizations are usually irreversible. In most instances, once introductions have been allowed to establish, no amount of money or effort can change the situation—much as is widely recognized for other lamentable and irreversible developments such as death, amputation, or the invention of disco music."

Because eradication of well-established populations has such a dismal record of success, Kraus next discusses long-term control. He largely focuses on the interdiction program for Brown Treesnakes (*Boiga irregularis*) on Guam, which aims to prevent the snake from reaching other areas, such as Hawaii, that are at risk of colonization by unintentional human transport of snakes. While this program has been successful in achieving its goals, it illustrates uncomfortable truths about the financial cost of long-term control and long timelines for research needed to develop effective control tools. The chapter ends with a discussion of limitations on our ability to manage introduced herps, focusing first on biology-related drivers (crypsis, high reproductive rates, and high population densities), then moving to social obstacles (disbelief in the magnitude of the problem, widespread intentional releases, etc.) and a general lack of commitment to developing adequate tools for the job. Taking the chapter as a whole, the take-home message is that reducing the rate of future invasions must be heavily reliant on prevention programs.

The final chapter (*Implications for Policy and Research*) offers a concise roadmap for those interested in developing solutions from a regulatory standpoint as well as researchers interested in fleshing out our limited scientific understanding of an increasing problem. Kraus presents a scathing indictment of regulatory structures and regulatory timidity in the United States and the European Union (the primary consumers of imported reptiles). Especially striking is the comparison of New Zealand with the U.S.; the former country has a single agency charged with preventing and managing exotic species, and this agency employs the precautionary principle when screening potential imports. Meanwhile, 36 to 40 federal agencies (and orders of magnitude more at the state level) have some role with invasive species in the U.S., and collectively they exhibit a history of regulating species only after they have become problematic invaders. The U.S. has a regulatory patchwork quilt with more holes than patches, and the result is sadly predictable—New Zealand has had zero exotic herpetofaunal establishments since the 1960s, while the U.S. has experienced at least 110 establishments during the same period.

Kraus also bemoans the 'dishonest market costing' in pet-trade-related herp introductions. He notes that in much of the world, animal importers and dealers are able to market herps at extremely low prices, allowing them to maintain high trade volumes including species that are poorly suited to captivity but which are abundant in source countries. Release or escape of animals by poorly informed, overwhelmed, or negligent owners is the near-inevitable consequence, and taxpayers end up picking up the tab for management of established populations. Kraus opines that costs of screening potential imports, educating purchasers, and controlling established populations should be internalized in the live animal trade, instead of being externalized by denying culpability and dumping the problem on others. Among other benefits, this raises the price of potential pets, promoting responsible care by owners and reducing the number of 'impulse buys' by those lacking the knowledge or resources to properly care for an animal.

The chapter concludes with a list of vital research questions that are needed to better understand the drivers of, and results of, herp introductions. This section could be a wellspring of ideas for new graduate students looking for thesis projects in applied herpetology. Kraus' recommendations on information that should be included in reports of new introductions or naturalizations should be of particular interest for readers of *Herpetological Review*, as this journal publishes

many Geographic Distribution notes for introduced herps. He recommends including information on when the introduction occurred, how many introductions were involved (and numbers of individual organisms when these data are available), identification of relevant pathways and motivations for release, and the status of the current population. With the recent demise of the journal *Applied Herpetology*, the importance of *Herpetological Review* and *IRCF Reptiles and Amphibians Conservation and Natural History* (which has taken over the peer-reviewed section on exotic herps from *Applied Herpetology*) as outlets for such reports will likely increase.

In a recent conversation, Kraus indicated no desire to continue the Sisyphean task of compiling literature records on this subject. Where will be found the sucker who will take up the mantle of Assembler of Arcane Introduction Records? While there are myriad, and often competing, databases that attempt to track introduced organisms, most of these rely on volunteers posting new finds to the site or a few flustered agency employees attempting to compile records across all organismal taxa. This approach lends itself to fragmentary and taxonomically or regionally biased perceptions of introductions. It is also worth noting that while Kraus has assembled a monumental dataset, this is likely an *under*estimate of the numbers and taxonomic diversity of introduced herps. By including only those records reported in the peer-reviewed literature, Kraus ignored media accounts, unpublished observations, and unpublished museum records. Accurate and complete introduction databases will be vital to answering some of the most basic questions that are of interest to preventing and managing future herp invasions, but the task is large and the payoff often small (Kraus notes that, "To put it bluntly, applied herpetologists don't get tenure").

Kraus' opus will be of great interest to a wide range of scientists, land managers, and policy makers, and its distribution would help dispel many of the common myths and laissez-faire attitudes about introduced herps. Unfortunately, the book's price will reduce its penetration in the groups that would most benefit from reading it (in fact, certain cheapskate herpetologists might accept an invitation to write a book review in order to get a free copy). The book is currently available online for about 20% less than the suggested price. It is really a steal at this price when considering its scholarly treatment of the subject matter, lively prose, and a trove of easily mined data.

Ethiopia is a special place, not only because of its history but also because of its stunning geographical and biological diversity, and the amphibians and reptiles of the area are no exception. Ethiopia and Eritrea are home to some 285 species of amphibians and reptiles and especially among amphibians, the level of endemism is high, with over 40% of all anuran species being endemic to Ethiopia. At the same time, the highlands of Ethiopia are among the most densely settled areas in Africa and the human pressure on the environment is immense, which makes this area one of the most threatened global biodiversity hotspots. It is, therefore, all the more laudable that the two foremost experts on the amphibians and reptiles of Ethiopia and Eritrea have teamed up to produce a guide book that will serve as a concise introduction to the herpetofauna of the area. As the authors state in the introduction, the targeted audience is less the seasoned herpetologist but more the interested novice and especially young, local herpetologists who are sorely needed to help preserve this unique place.

The book is lavishly illustrated with over 380 color and 25 black and white photographs, in addition to some 23 black and white drawings and 282 distribution maps. The photographs are usually arranged two to a page but a fair number

occupy a full page. With a few exceptions, the photographs are of very good quality although the colors seem a little off (a little faded or slightly too saturated) in quite a few images.

Following the table of contents, the preface, and acknowledgments, the book begins with a chapter on the zoogeography of North East Africa. This chapter introduces the various ecosystems of the area, their main characteristics and dominant plant species, and briefly describes the geological history as well as more recent changes. The chapter contains 23 color pictures illustrating a number of different habitats and a simple black and white map of the physical geography of Ethiopia and Eritrea. The color photographs are very instructive and give the reader a good idea of the various habitats but the map is too small and pretty dull and does not stand up to the quality of the rest of the illustrations in this book. It would have also been nice to include a map of the different vegetation zones and perhaps another map with rainfall data. The next, short chapter highlights conservation issues that pertain to the Ethiopian and Eritrean herpetofauna.

The following four chapters deal more specifically with amphibians and reptiles. The first of these provides a very general introduction to the two groups, their evolutionary history and some very brief information on their ecology, physiology, reproduction, etc., and the information provided here indeed only serves as a first introduction for someone who really does not know much about amphibians and reptiles. The second chapter gives advice on observing and collecting amphibians and reptiles. This chapter is more detailed than the previous and gives useful advice for collecting and handling amphibians and reptiles. This chapter appears to have been written with the beginner in mind and it would have been good to point out how important it is to preserve tissue samples in ethanol, particularly for specimens from some seldom visited places within Ethiopia and especially Eritrea. The third chapter briefly explains the rationale behind scientific nomenclature and the following short chapter provides some general advice on identifying amphibians and reptiles and how to use the identification keys provided in the book.

The more than 600 pages that follow are dedicated to the familial, generic and species accounts. The familial and generic accounts are quite short. The species accounts differ in length but comprise on average two thirds of a page to a full page. Species accounts are subdivided into a section describing the species and another section that provides information on its distribution and ecology. Almost all species accounts are accompanied by a small distribution map with point distributions mapped onto it and at least one color photograph. The species accounts are necessarily rather concise but contain enough information to help identify specimens and also provide a good summary of what is known about the distribution and some information on ecology. In the amphibian accounts, information on the conservation status is listed as a separate section whereas in the reptile accounts this information, where available, is integrated into the "distribution and ecology" section. Some recent taxonomic changes have not been implemented here and the taxonomy applied is best described as conservative. This is particularly apparent in gekkotan (Han et al. 2004) and amphibian (Frost et al. 2006) taxonomy, where recent changes have not been incorporated even though these are widely accepted now.

Following the species accounts are a gazetteer, a glossary, a bibliography with a "selection from the most relevant work published in or after 1970" as well as a taxonomic index and an alphabetic list of the amphibian and reptile species of Ethiopia and Eritrea with taxonomic authors.

In addition to the taxonomic accounts, the book contains keys to all genera of frogs, lizards, snakes, and turtles found in the area. Each key is accompanied by a schematic drawing illustrating the main diagnostic features used in the keys, which should help the novice navigate her or his way through the keys. Additional keys are provided for speciose genera although there seems to be no consistent pattern as for when a key is provided or not. The general rule seems to be to have keys for genera with seven or more species although for some, like *Agama* with seven species no key is provided whereas a key to the six species of *Platyceps* is included. I found that slightly puzzling, but I am sure that there are good reasons for this. Somewhat more puzzling is the pattern by which taxa are arranged in the book. Orders and families are arranged alphabetically (with one exception) whereas there is no consistent pattern for listing genera or the species within a genus. This might not seem to be much of an issue but it quickly becomes a nuisance if one has to go back and forth between species accounts within a species-rich genus, which either means frantically leafing through the book or constantly referring back to the table of contents. This is definitely something that should be rectified in any future edition.

Edition Chimaira publishes a number of different series, the most prominent of which are the "white" (also known as the Frankfurt Contributions to Natural History), and the "black" series. The present book is published in the white series, which is smaller in format than the black series. Given the substantial page count, it might have been better to publish this as part of the slightly larger black series, because the current size and especially weight of the book means it is actually not too dissimilar from a brick. I personally would not want to have to carry it into the field but it definitely seems to be sturdy enough to survive more than one field exposure, if you keep it dry of course.

The verdict? There are many small things to fret about but at the end of the day I found myself picking up this book far more often than I initially expected. This book is an excellent contribution to literature on African herpetology and every person with a remote interest in the herpetofauna of Ethiopia and Eritrea, and Africa more generally, would want to have this book in her or his library. It is admittedly not cheap but

the print quality just about justifies the price. Sadly, I fear that the asking price will very likely prevent this book from reaching a circulation in Ethiopia or Eritrea that will exceed single digit figures. On the other hand, for people from overseas working in the area, it would make a great and surely much appreciated gift for a local collaborator.

By any measure, the last decade has been a challenging one for those involved with either the private reptile hobby (or, if one prefers the more grandiose term, industry), or the professional worlds of zoo and academic herpetology. For amateur enthusiasts and "herpetoculturists," flush with the optimism born of the explosion of these fields in the 1990s, the last decade has been a sobering wake-up call. With the rising popularity of keeping, breeding, and observing/photographing reptiles and amphibians in the wild has come push-back, in the form of legislative restrictions at the local, state, and national levels in the United States. Concurrently, zoological institutions have found that they are far from immune to these same regulations, and in many cases both the acquisition of new specimens and disposal of surplus animals have become equally problematic.

These regulations, justified or not, have been fueled, to a great extent, not only by lobbying from animal rights groups such as the Humane Society of the United States and People for the Ethical Treatment of Animals, but by sensationalized, unflattering, and (at times) dubiously factual depictions of reptile professionals and enthusiasts in the popular media. So it was with some trepidation that I approached Jennie Erin Smith's new book, an exhaustive account of the careers of three of the reptile world's most well known (and, truth be told, notorious) characters: Hank Molt, Tom Crutchfield, and Anson Wong. Although certainly of interest to herpetologists and reptile enthusiasts of all stripes, this book is aimed at a mass audience, and I worried that here I would find more of the same, the literary equivalent of those Animal Planet documentaries—heroes and villains portrayed in black and white terms, leaving the reader with little choice but to be led, cheering, to the author's inevitable and foregone conclusion.

I also expected the kind of ludicrous errors of scientific fact one commonly finds when a journalist writes on a herpetological subject. This passage on the very first page, in which Smith introduces (and attempts to define, in a lighthearted yet dismissive manner), the term "herpetoculture," did little to ease my discomfort:

> "...it [herpetoculture] sounded like "herpetology", but you needed a Ph.D. to be a herpetologist. If you woke up to find your pet snake had laid eggs, you were a 'herpetoculturist'."

Not exactly accurate on either count and guaranteed to annoy herpetologists and herpetoculturists alike.

However, as my reading progressed, I am pleased to report that I found quite the opposite of that which I feared. Over a decade's time, Smith immersed herself in the lives of her three protagonists, as well as those of a host of supporting characters from all sides of the law. What she found, unsurprisingly, were big plans, big egos, big mistakes, quite a lot of villainy, and a notable lack of heroes. In a disarmingly transparent style, she is content to lay out the facts and allow a truly fascinating story to speak for itself. I could detect very little personal bias in her prose, and, even better, factual errors were all but nonexistent. Smith is obviously either a bit of an enthusiast herself, ran her manuscript past some experts, or, more likely, both.

Despite the tawdry, unflattering, often illegal nature of many aspects of these stories, surprisingly few facts are seemingly in dispute. For those that are, Smith is careful to give the accounts of all protagonists equal weight, and generally refrains from editorializing, leaving the reader to reach his or her own conclusion. Given the information available, that conclusion is often pretty clear.

Most of the book is devoted to Molt and Crutchfield, and from the mid-1960s to the present, their careers evolve against a background of the great change that swept across the face of herpetology and reptile-keeping ("herpetoculture" had not yet been coined) in those decades—not incidentally including the ever-widening gap between academic herpetologists on the one hand, and those from the zoos and the private sector on the other. Two more fascinating personages could hardly be imagined.

The section on Anson Wong, the successful and wealthy Asian animal dealer, almost seems an afterthought, and almost pasted-on, leaving one curious to hear more about his exploits earlier in life. Interestingly, Wong is the only one of the three currently still imprisoned, in Malaysia, for his illegal activities.

Tom Crutchfield comes off as the most sympathetic character, a charming, brash, overbearing, somewhat volatile rogue, seemingly dismissive of authority yet, on another level, longing for acceptance and success in the mainstream of herpetology. In this respect, there are many like him out there, frustrated herpetologists who, in one way or another, lack the patience, focus, or other scholarly character traits that lead to success in the academic arena. Yet they certainly do not tend to channel that kind of frustration into illegal activities such as wildlife smuggling. Despite his illegal activities involving smuggled wildlife, one gets the impression that Crutchfield harbors a deep love and respect for reptiles, and would draw the line at doing anything that would have negative conservation consequences.

Hank Molt is more difficult to understand, as his passion for rare and unusual reptiles quickly combines with a seemingly congenital need for adventure and stimulation to push him far beyond the boundaries of the law, and even morality. Though obviously a man of considerable intelligence, he repeatedly makes fatal (and avoidable) errors that deliver him into the hands of the authorities. And yet soon he is back at it, seemingly addicted to the thrill of pulling scams, uncaringly ripping off friend and foe alike (and his treatment of his "friends" is profoundly base and deceitful—the term "sociopath" comes to mind here). As can be imagined, Molt's tale is a roller coaster ride, but certainly not boring!

The authorities, United States Fish and Wildlife Service agents most notably, but also federal prosecutors and the wildlife departments of various countries, are not exactly heroes here either. Personal vendettas, selective prosecutions, amateurish mistakes, sweetheart deals, bribery, and kickbacks are portrayed as commonplace. Reptile dealers are sent to prison while the famous zoos and museums, which actively encouraged "acquisition" (read smuggling) of protected species, are shielded by political connections. If personnel from these institutions were not fully aware of the illicit activities, they certainly turned a blind eye as long as they obtained their sought-after species.

And then there was the blatant hyperbole and self-promotion by U.S. officials, as Smith notes:

> "The Time Magazine story, which relied heavily on Agency sources, estimated the global illegal reptile trade as worth between $10 billion and $20 billion annually."

The above figures would have placed international reptile smuggling on a par with the global arms trade, at a time when TRAFFIC estimated the total LEGAL live animal trade (including ornamental fish, birds, reptiles and amphibians, and mammals at about US $826 million a year (with smuggling considered the barest fraction of that) (Roe et al. 2002). An agency official later concedes that their figures were made up out of whole cloth.

Caught in the middle were the zoos, increasingly desperate for rare specimens to attract visitors. At times they bankrolled and even explicitly supported the smugglers in private, with paperwork and "letters of introduction" on zoo letterhead. But in public they were very careful to appear spotless, and voiced nominal support for conservation organizations and NGOs bent on curtailing smugglers and even the wildlife trade itself. Of course this path was doomed to failure from the beginning, and good zookeepers and curators eventually lost their careers when the house of cards finally tumbled.

The big losers in this story are, of course, the thousands of individual reptiles and amphibians swept up in the illicit wildlife trade. With rare exceptions (the brazen theft of over 70 Ploughshare Tortoises from the Jersey Wildlife Preservation Trust compound in Madagascar, for example), the numbers involved apparently had scant effect on wild populations or species. But the carnage among the individual animals is difficult at times to comprehend. Entire shipments of Fiji Iguanas, Boelen's Pythons, Gray's Monitors, and countless other reptiles perished in a variety of nasty ways: in the country of origin due to brutal capture techniques, through being smuggled in horribly cramped and unsuitable containers, or from incompetent husbandry at the hands of government authorities and even zoos after confiscation.

Noteworthy is the fact that nearly all the fabulously valuable reptiles that were the object of smugglers in the 1970s and 1980s—Bismarck Ringed Pythons, Ridgetail Monitors, *Rhacodactylus* geckos, Green Tree Pythons, Blue-tongued Skinks—are now captive bred so frequently and in such quantity that their value no longer justifies the risks associated with smuggling, or, in many cases, even the cost and hassle of legal importation.

Stolen World is a sad, yet fascinating, look at all sides of illegal reptile trafficking. It is that rare book that will appeal to the masses as a good read, and yet simultaneously can be regarded as an important one as well. It should be read by anyone interested in truly effective conservation of reptiles and amphibians.

Catching up with all the new knowledge being accumulated on snakes, published in diverse journals all over the world and in many languages, is a time- and energy-consuming exercise. This is particularly true for the first decade of this century, which has already seen impressive progress on a number of aspects of snake biology and evolution. Fortunately for all naturalists and herpetologists, every few years one or more researchers seem to tackle this arduous task, for the benefit of the entire community. This is especially valuable when it is done by a skilled herpetologist such as John C. Murphy, who is an active field researcher and has an extensive experience in making scientific knowledge accessible to the public, as evidenced by his recent comprehensive volume on homalopsid snakes (Murphy 2007).

The new book is illustrated by 84 snake photos, plus two dozen others, mainly of other reptiles, as well as diverse drawings and figures. All are in black and white. It is thus definitely not a coffee table book, but rather a book to learn from. *Secrets of the Snake Charmer* focuses on snake research done during the first decade of the 21st century. Although released in April 2010, the book deals with literature through the beginning of the same year. Literature references are not indicated in the main text, but the commented bibliography (pp. 321–380) is organized by chapter and thus easily allows the identification of sources of the information presented.

As noted by the author (p. xii) "snakes can serve as a window to open the ideas of ecology and evolution to people otherwise distracted by religion, junk TV, technological gadgets, and sporting events." Although packed with information the book is written in an accessible style and makes a pleasant read for both professional herpetologists and amateurs. The selection of subjects dealt with in the main text (pp. 1–320) is wide: snake evolution, fangs and venom apparatus, predation, defense mechanisms, etc. The 14 chapters are themselves divided into numerous focal subtopics. Many topics are enlivened by the author's anecdotes based on personal experiences in the field.

A weak point of the book is the 'Index to Scientific Names and Authors' (pp. 389–400). The text uses snake common names (e.g., Burmese Python, European Cat Snake, King Cobra, Little File Snakes, Vine Snakes) extensively, and it would thus have been useful to include them in the index as well. In many cases the common name is not associated in the main text with the corresponding scientific name, and the exact identity of the snake is thus not always easy to determine. Further, many scientific names cited in the main text are not included in the index (e.g., *Coelognathus radiatus*, *Colubroelaps nguyenvansangi*, Crotalidae, *Enhydrina schistosa*, *Enhydris polylepis*, *E. subtaeniata*, *Oxyuranus microlepidotus*, *Pseudonaja textilis*, *Vipera aspis*), or only at the generic level, or not for all pages where they are cited in the main text. Among the non-reptilian scientific names mentioned in the main text, some are listed in the index (e.g., *Felis catus*), some not (e.g., *Rattus villosissimus*). As for the scientific names, authors listed in the main text are not all listed in the index either, and in any case the utility of an author index in such a work seems limited to us. There are some mistypings, mainly in scientific names and proper nouns, but not to the extent that they detract appreciably from the book.

Despite the few negative points noted, we generally had an excellent opinion of this new book. It makes a very good read for anybody seriously interested in snakes and who wants to know more about them and we recommend it to both interested novices as well as seasoned herpetologists.

Lizards in an Evolutionary Tree: Ecology and Adaptive Radiation of Anoles

By Jonathan B. Losos. 2009. University of California Press (www.ucpress.edu). xx + 527 pp. Hardcover. US $95.00. ISBN 978-0-520-25591-3 (Paperback US $49.95. ISBN 978-0-520-26984-2).

DANIEL PINCHEIRA-DONOSO
Centre for Ecology and Conservation,
College of Life & Environmental Sciences,
University of Exeter, Streatham Campus, Exeter EX4 4PS, Devon, United Kingdom
e-mail: D.PincheiraDonoso@exeter.ac.uk

The history of evolutionary theory is tightly linked to vertebrates and islands. The year of evolution (2009) has reminded biologists and non-biologists that finches in the Galapagos Archipelago inspired some of the most provocative thoughts in Charles Darwin's mind. Since then, these ecologically diverse birds have gained a privileged place as promoters of one of the deepest revolutions in human thought. Far away from the Galapagos and from Darwin's itinerary, another group of vertebrates on another group of islands quietly awaited their own opportunity to gain a privileged place in the history of science. In *Lizards in an Evolutionary Tree*, Jonathan Losos tells the story of Caribbean anoles and their contributions to evolutionary biology. For over five decades anoles, particularly the genus *Anolis*, have been the subject of an extraordinary wealth of research dealing with most aspects of the fields of ecology and evolutionary biology. These lizards have not only been useful model systems, anoles are special because they have been instrumental in the development and refinement of theories that have shaped our view of ecological and evolutionary dynamics, contributing greatly to our understanding of major theories such as adaptive radiation and speciation. Anoles, therefore, deserve a great deal of attention from those interested in ecological and evolutionary processes as they occur in nature. However, to read and assimilate the monumental amount of literature on anole evolutionary ecology would require a large part of one's career. The good news is that Losos has done just this, achieving an extraordinary synthesis in a single, solid, entertaining, and comprehensive volume.

The book is impeccably well-organized and its 17 chapters cover the entire diversity of primary theoretical and technical fields relevant to understanding the evolution of adaptations and the origin of new species. While the many footnotes (477 on 409 pages)can be somewhat distracting , they typically contain important relevant information and are worth the pause from the main text. After a couple of pages these footnotes become pleasing distractions because they often also contain entertaining stories that tend to be absent from scientific books of this quality.

In the first three review chapters (2–4, Chapter 1 is a general introduction to the problem of evolution), Losos provides a fine account of the most important aspects of anole diversity. Information in these chapters covers themes as varied as species concepts, competition, key traits involved in sexual and ecological performance, biogeography, reproductive isolation, and arguably one the most comprehensive treatments about anole ecomorphs (and non-ecomorphs) available in the literature. In these chapters, the reasons why these lizards are excellent model organisms for evolutionary and ecological research become apparent. Losos also makes the case for how critical species-specific natural history information is for understanding evolutionary processes. Clear maps and astonishing color pictures contribute to making these chapters accessible and enjoyable to read.

In chapters 5–7, the book turns to phylogeny. Of particular interest for all comparative biologists are timely discussions of the application of phylogenetic approaches to evolutionary questions (Chapter 5), a field in which the author himself has made important contributions. From this chapter, it becomes clear that not all phylogenetically based analyses can be taken at face value. For example, Losos shows why ancestral reconstructions (widely used in the mainstream scientific literature) under several circumstances should be interpreted with caution. Chapter 6 discusses the phylogeny of anoles, and explains how this information has unravelled the biogeographic history of the group. In this phylogenetic framework, evolutionary changes that accompany the selective challenges encountered in newly colonized areas can be appropriately interpreted. This information is used to discuss the roles of divergent and convergent adaptation that have shaped anole morphologies, and remarkable historical scenarios emerge. For example, a well-established observation in biogeography is that colonization between mainland and islands is typically unidirectional, from the former to the later. Colonization in the other direction is thought to be less likely because island species are regarded as weak competitors if placed in continental ecological arenas. However, phylogenetic evidence suggests that anoles have not only recolonized the continent from the Caribbean islands several times, but also that these adventurous colonizers have been remarkably successful establishing an extraordinary lineage of almost 130 species. Patterns of dispersal and speciation

emerge, and Chapter 7 covers the exciting topic of ecomorphological evolution in great detail. The predictability of body size and shape evolution are explored, with interesting accounts of phylogenetic patterns of ecomorphs and the debated, but intriguing, idea of evolution by character displacement. These chapters make a strong case for how autonomous the process of adaptation can be, and how crucial the effect of selection is to shaping the functional, causal, and dependent linkages between environmental pressures and phenotypes (see Hurst, 2009, for a discussion of the genetics of selection effects). As Williams (1966) vividly argued in his famous book, adaptation should be accepted as an explanation when other alternatives have failed. This imposes a difficult challenge as alternative hypotheses often offer appropriate mechanistic pathways to explain organismal features. However, as Losos shows in his book, the adaptive explanation for Caribbean *Anolis* evolution is strongly supported from a number of empirical angles, including replicated associations between ecological demands and morphological traits and functional capabilities. Losos also emphasizes that not all *Anolis* are the same, and that this idealized evolutionary story is much more complex on other islands and on the mainland. The field of ecomorphology is, in summary, richly presented in this section.

Losos broadly reviews the biology of anoles in the next section of the book (chapters 8–13), covering all aspects of anole interactions, from causes to consequences, and from ecology to sexuality. These broad discussions even touch on topics that lizard biologists rarely mention, including potential intelligence and sleeping habits. Chapter 8 includes a diversity of topics that are rarely known in such detail in any single genus, such as reproduction, growth, lifespan, parasites, predators, diet and other forms of ecological interactions. Chapter 9 focuses on one of the most exciting fields in evolutionary biology, the origin and impact of intraspecific interactions to determine social and sexual dynamics, with a clear review of the main principles of sexual selection theory. The discussion includes the unavoidable phenomenon of sexual dimorphism, a remarkable and debated outcome of evolutionary diversification within species. Losos presents a clear, unbiased and comprehensive review of the problem of phenotypic differences between the sexes. The chapter gives deserved weight to the two main explanations proposed by Darwin (1874), natural selection on ecological preferences or sex roles, and sexual selection. The focus of the analysis is primarily on the evolutionary forces that determine the direction of patterns of sexual dimorphism and the outcome. However, no particular detail is given to the complex genetic factors that allow or constrain divergence in alternative, sex-specific directions in the first place, once selection has provided the evolutionary impetus for the expression of this phenotypic divergence (Fairbairn et al. 2007). Chapter 10 presents a particularly informative review on how temperature, humidity, light and other factors govern the ways anoles exploit common areas by means of micro- and macro-environmental segregations. Once again, the pivotal role of anoles in the establishment of current theories and models is highlighted, as Losos reminds us how these lizards have been instrumental in the development of the field of thermal biology.

From Chapter 11, the book turns into a fascinating and dynamic synthesis of information from previous chapters and the focus shifts to the broad fields of adaptive radiation and speciation, which represent the real essence of evolution. In chapters 11–13, the theory of adaptive radiation is introduced from the multiple angles required to understand how evolutionary mechanisms (essentially, natural selection) ultimately drive evolution. A brief but clear theoretical background to adaptive radiation is presented, in which Losos emphasizes that this process is important because it results in the evolution of disparate ecological and phylogenetic diversity from single ancestors, whereas the timing of diversification (the well known "early burst") is simply one of the features of the process, rather than a crucial concept involved in its definition. These three chapters offer a complete review of the anole adaptive radiation, where studies of community ecology (from predators to parasites), field manipulation of free-ranging lizards, and phylogenetics provide evidence of the effects of divergent natural selection on adaption and cladogenesis. Interesting syntheses of field evolutionary genetic experiments across generations and of geographic variation as an encouraging avenue to investigate adaptive radiations are presented.

The integration becomes still stronger in chapters 14–16, where the evolutionary diversification of anoles is reviewed in great detail. In these chapters, as in the rest of the book, no theoretical biases or biased speculations are found. All major theories of diversification are incorporated into the discussion, including the largely demonstrated fact that natural selection is a prominent driver of speciation. However, several controversial views, such as founder effect speciation (Coyne and Orr 2004), are also included in the discussion. As can be expected for an island adaptive radiation, due weight is also given to geographical models of speciation (allopatry, sympatry, parapatry). Some fascinating explanations of selection-based speciation are presented, such as the potential impact of head-bobbing and variation of dewlaps on the breakdown of gene exchange between diverging species. Phylogeny, rates of evolution, sexual dimorphism and niche expansion as agents of diversification, key innovations, island biogeography theory, ecomorphs, and the adaptive landscape approach, among others, are dynamically recalled in these final chapters. The book concludes with Chapter 17, in which an overview touching on other adaptive radiations elegantly summarizes the extensive information presented in the preceding chapters.

Throughout the book, Losos provides responsible and unbiased discussions and interpretations of the available evidence, and still better, maintains the tendency to complement certain ideas with novel speculations about the factors involved in anole lizard evolution. Although many scientists often feel reluctant to take intuitive speculations into account, it cannot be denied that scientific progress relies importantly on the freedom of imagination to suggest alternative explanations for phenomena. Some of these speculations may be proven incorrect, but they inspire the reader to think freely about possible explanations for evolutionary questions.

Finally, an important question that many potential readers of Losos's book may be asking is whether this is primarily about anole lizards or about evolutionary ecology. Many might immediately argue that this book is about evolutionary ecology. However, I believe one of the greatest achievements of Losos is the integration of fields he provides in this book. Losos, more than most evolutionary biologists, makes a strong case that species-level natural history is critically important to fully understand a complex multi-phenomena process like evolution. Hence, Losos has managed to write a book that will serve a broad audience. It represents one of the best and most comprehensive synthetic treatments of the theories of adaptive radiation and speciation based on the empirical context of a specific model system, but it also provides a thorough review of the diversity and natural history of anoles. It has to be said, however, that this is a decidedly scientific book, and clear understanding of theoretical concepts is paramount to the story it tells. For example, despite the enormous diversity of theories encompassed by Losos in this book, the introductory text for each of these ideas is generally brief. Hence, the author implicitly assumes that readers are familiar with the main concepts. However, in this book jargon and simple language are balanced, making it accessible to a broad audience, while maintaining a consistently high level of scholarship. This book is, therefore, a true representation of Einstein's quote "everything should be made as simple as possible, but not simpler."

PUBLICATIONS RECEIVED

How Vertebrates Left the Water

By Michel Laurin. 2010. University of California Press (www.ucpress.edu). Hardcover. xv + 199 pp. US $34.95. ISBN 978-0-520-26647-6.

This is an English translation, with minor updates, of Laurin's original French book of 2008. It is concise, clear, and well written. The book serves both as a summary of the important changes that took place in this most important of vertebrate transitions and as an argument for parsimony and phylogenetic nomenclature. It begins with a critique of rank-based nomenclature and offers phylogenetic nomenclature as a solution to aspects of instability in the prevailing system. This is followed by an explanation of parsimony-based methods of phylogenetic reconstruction and a discussion of molecular and paleontological dating. The introductory chapter is rounded out by brief treatments of homology, the geological time scale, and paleogeography. Laurin then considers what living taxa can tell us about the conquest of the land before addressing such topics as the evolution of limbs, the diversity of Paleozoic stegocephalians, and the adaptation of the skeleton, respiratory system, skin, and sensory organs to life on land. The slender volume closes with a glossary of more than 50 terms, a bibliography of more than 150 entries, and a combined subject/taxon index. The book draws heavily on the author's works from the early 1990s onwards and unabashedly promotes his views on a number of topics. At the same time, it does a remarkable job of distilling down each of the subjects addressed to just a few clear, concise, information-packed pages. The book ably succeeds in the author's desire to make the material accessible to those with little prior knowledge in the field and, indeed, offers even novices a succinct view of how modern vertebrate paleontologists test hypotheses about the evolution and biology of extinct organisms. It may be especially useful for herpetologists, systematists, and anatomists whose work

is chiefly or exclusively neontological and who would like an up-to-date primer of the events of the Paleozoic that set the stage for the modern world of terrestrial vertebrates.

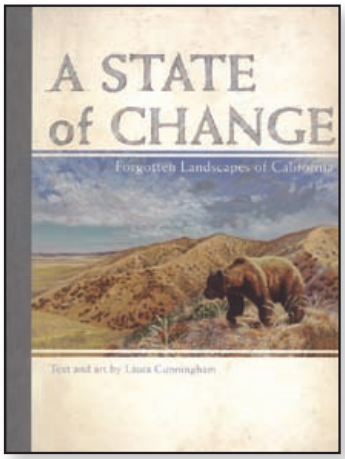
L'Interprétation des Nomes Grecs er Latins d'Animaux Illustrée par le Cas du Zoonyme Sēps-Seps

By Liliane Bodson. 2009. Académie Royale de Belgique, Mémoire de la Classe des Lettres, Collection in-8°, 3° série, Tome XLIX, n°2062 (www.academieroyale.be). Softcover. 368 pp. 30,00 Euro (approximately US $42.00). ISBN 978-2-8031-02631.

This French language memoir explores the interface between classical studies and zoology and has a significant herpetological component. The ancient Greek word "sps," originally meaning "putrifying sore" (hence the word sepsis), was subsequently Latinized and applied to certain types of venomous animals known in the ancient world. The author examines both written and iconographic sources in order to determine the identity of the animals to which the term "seps" has been applied and the anthropological and toxicological criteria met by these disparate taxa that resulted in their inclusion under this term. This specific example is used to investigate the Greek and later the Roman approach to knowledge about the animal kingdom and is further used as an example that illustrates the way in which ancient sources can provide information about the ecology and zoogeography of animals in the ancient Mediterranean. Based on its usage by 31 authors over nearly two millennia, the term "seps" is shown to have been applicable to snakes, lizards, centipedes and caterpillars, with the majority of uses, and virtually all before the 6th century A.D., being herpetological. Additional iconographic sources, as well as modern interpretations of early uses of the term are also considered and the identities of the animals intended by ancient authors are carefully deduced through the comparison of the characteristics of the "seps" and modern knowledge about the distribution and biology of candidate species. Viperid snakes and scincid lizards are most consistent with the ancient data which, in many cases, are detailed enough to allow specific identification. All Greek and Latin sources have been translated into French and much of the data are summarized in convenient tables. The work is supported by a thorough bibliography of 40 pages and six indices (ancient sources, modern authors, Greek and Latin vocabulary, scientific names, French scientific and vernacular names of animals, and a general index) and is accompanied by four color plates and several black and white illustrations. Although highly specialized, this work will be of interest to herpetologists, and zoologists in general, who have an interest in history, as well as to ethnozoologists, anthropologists, and classicists.

Lista Anotada de los Anfibios y Reptiles del Estado de Hidalgo, México

By Aurelio Ramírez-Bautista, Uriel Hernández-Salinas, Fernando Mendoza-Quijano, Raciel Cruz-Elizalde, Barry P. Stephenson, Victor D. Vite-Silva, and Adrian Leyte-Manrique. 2010. Universidad Autónoma del Estado de Hidalgo and CONABIO, Pachuca, Hidalgo. 104 pp. Softcover. US $25.00 (available from Bibliomania! www. Herplitsales.com). ISBN 978-607-7607-39-7. [In Spanish]



Here is another addition to the rapidly expanding list of state or other regional works concerning Mexican herpetofauna. This volume is the first treatment for the Mexican state of Hidalgo, which straddles the Sierra Madre Oriental of eastern-central Mexico, a region of substantial topographic and habitat diversity. This is an introductory work, offering an annotated list of species along with known localities, as well as preliminary analyses of the herpetofauna based on levels of endemism and association with specifc biotic communities. The authors include an overview and color photograph of each the 12 major vegetation types. There are four principal biogeographic regions within Hidalgo: Sierra Madre Oriental, Altiplano Mexicano (Central Plateau), La Faja Volcánica Transmexicana (Transvolcanic Belt), and Golfo de Mexico (Gulf of Mexico). Despite its small size (20,500 km^2, equivalent to the US state of New Jersey), Hidalgo boasts 173 species of amphibians and reptiles, emphasizing Mexico's status as a biodiversity hotspot. Taxonomically, the herpetofauna consists of 14 salamanders (all but 3 are plethodontids), 40 anurans (including the introduced *Lithobates catesbeianus*), 3 turtles (all *Kinosternon*), 37 lizards (including an undescribed species of *Xenosaurus*), and 78 snakes (including an undescribed species of *Rhadinaea*). Another five species (one anuran, four lizards) are listed as potentially occurring within the state. Of the 173 confirmed species, four are new state records: *Hyla euphorbiacea, Epicta goudotii, Thamnophis scaliger*, and *Rhamphotyphlops braminus* (introduced). Color photographs are provided for 90

species, in addition to 32 black-and-white images that depict an additional 12 species. A detailed map of Hidalgo with key reference points, as well as a vegetation map, would be helpful additions for readers not intimately familiar with the regional geography. The authors have produced an important foundational work that sets the stage for further research.

A State of Change: Forgotten Landscapes of California

By Laura Cunningham. 2010. Heyday Books, Berkeley, California (www.heydaybooks.com). 350 pp. Hardcover. US $50.00. ISBN 978-1-59714-136-9.

Biologist / illustrator Laura Cunningham has combined her artistic talent with a keen knowledge of contemporary and ancient communities to produce a masterpiece of historical ecology, accessible to a broad range of readers. Cunningham draws on the works of various researchers across diverse disciplines (archaeology, paleontology, geology, ecology) to describe what these same communities looked like prior to the arrival of European colonizers—before rivers were dammed for hydroelectricity, before vast swaths of land were converted for agriculture or cities, before wetlands were drained—and in some cases, much earlier (40,000 ybp). The illustrations range from beautiful oil paintings to pencil sketches. Particularly fascinating are the pairing of ancient and modern views of the same place. Thus, we are treated to a biologically informed rendering ("paleo art") of Santa Barbara 500 yrs ago alongside a contemporary photo of the same scene. Historical information is footnoted throughout the text, permitting readers to track down primary sources. Although this is not a herpetological work, per se, a few amphibians and reptiles receive featured treatment: Panamint Alligator Lizards (*Elgaria panamintina*), Amargosa Toads (*Bufo nelsoni*), and Foothill Yellow-legged Frogs (*Rana boylii*). Species are indexed by common name, although an appendix lists both common and scientific names.

Eagle Mountain PUBLISHING, LC

SPECIAL LIMITED TIME OFFER

To assist SSAR with the current membership drive, until August 15th 2011, we will be offering our titles to Society members at a 40% discount.* Please inform non-members of this great offer, so they can receive this discount if they join SSAR.

Conservation of Mesoamerican Amphibians and Reptiles
Edited by Larry David Wilson, Josiah H. Townsend, and Jerry D. Johnson

SAVING SEA TURTLES

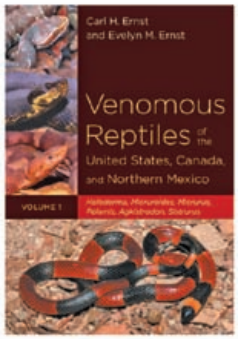
Extraordinary Stories from the Battle against Extinction

James R. Spotila

Due to human actions, once-plentiful sea turtle population levels plummeted throughout much of the twentieth century. James R. Spotila has been at the forefront of sea turtle research and conservation for decades. His inspirational story of dedicated individuals, creative endeavors, and adventure reveals what is being done and what else we must do in order to ensure that these magnificent creatures continue swimming in the oceans.

240 pages, 12 illustrations, $24.95 hardcover

FROGS



The Animal Answer Guide

Mike Dorcas and Whit Gibbons

Frogs are amazingly diverse—ranging from the massive goliath frog, which weighs several pounds, to the recently discovered gold frog, which measures a mere three-eighths of an inch when fully grown—and have inhabited the earth for more than 200 million years. Today, however, these amphibians face more challenges than any other vertebrate group. In this fun and informative book, herpetologists Mike Dorcas and Whit Gibbons answer common and not-so-common questions people may have about these fascinating animals.

192 pages, 97 illustrations, $24.95 paperback

VENOMOUS REPTILES OF THE UNITED STATES, CANADA, AND NORTHERN MEXICO

Volume 1

Heloderma, Micruroides, Micrurus, Pelamis, Agkistrodon, Sistrurus

Carl H. Ernst and Evelyn M. Ernst

Carl and Evelyn Ernst have completely revised their landmark reference *Venomous Reptiles of North America*. Volume One of this definitive work presents dramatically improved species accounts of the venomous lizards and elapid and viperid snakes found north of Mexico's twenty-fifth parallel.

392 pages, 114 illustrations, $75.00 hardcover

9th Annual Symposium *on the* Conservation *and* Biology *of* Tortoises *and* Freshwater Turtles

August 14-17, 2011 in Orlando, Florida

Join us in at the Rosen Plaza Hotel in Orlando in August for the largest gathering of non-marine turtle biologists and enthusiasts in the world. Last year's conference welcomed presenters from 22 countries, providing an unmatched opportunity for networking and forging conservation partnerships.

The conference represents a great value with low registration fees that include all evening events at no additional cost. Discounts are available for TSA members and students, in addition to early registration discounts for those that register prior to July 8. Travel grants are available on a limited basis for presenters. For all conference details, visit the Turtle Survival Alliance website: **www.turtlesurvival.org**

INFORMATION FOR CONTRIBUTORS

Herpetological Review is a peer-reviewed quarterly that publishes, in English, articles and notes concerning the study of amphibians and reptiles, as well as book reviews, commentaries, regional and international herpetological society news, and letters from readers directed to the field of herpetology. Articles reporting the results of experimental research, descriptions of new taxa, or taxonomic revisions are not published in ***HR***, but should be submitted to the ***Journal of Herpetology*** (for information, please refer to: http://www.ssarherps.org/pages/JHinstr.php). To submit a manuscript to ***HR***, please consult the SSAR webpage at:

<http://www.ssarherps.org/pages/HRinfo.php>

REPRINTS AND PAGE PROOFS

Reprints of notes or articles published in ***HR*** may be ordered through EZReprints (EzReprint@odysseypress.com), an online reprint ordering system. Authors will receive email notification as the issue goes to press. Page proofs are sent electronically to authors of all articles, book reviews, and obituaries, but are not sent for natural history notes or geographic distribution notes. Proofs are sent as pdf files approximately 2–4 weeks prior to publication. Corresponding authors who are current members of SSAR will automatically receive free, screen-resolution pdf files of their articles or notes.

ADVERTISING

Herpetological Review accepts commercial advertising. Rates and copy information are available from the SSAR web page (http://www.ssarherps.org/pages/HRinfo.php).

Herpetological Review (ISSN: 0018-084X) is published quarterly (March, June, September, and December) by the Society for the Study of Amphibians and Reptiles at Central Michigan University, Department of Biology, 217 Brooks Hall, Mt. Pleasant, MI 48859, USA. Periodicals postage paid at Mt. Pleasant, MI 48859 and at additional mailing offices. All rights reserved. No part of this periodical may be reproduced without written permission of the Editor, except that authors and their agents are permitted to reproduce and distribute their own articles and notes. **POSTMASTER:** Send address changes to Breck Bartholomew, SSAR Publications Secretary, P.O. Box 58517, Salt Lake City, UT 84158. **MISSING OR DAMAGED ISSUE?** Please notify Breck Bartholomew, SSAR Publications Secretary (e-mail: ssar@herplit.com) for a replacement.

SSAR PUBLICATIONS

SSAR publishes seven different series: *Journal of Herpetology, Herpetological Review, Facsimile Reprints in Herpetology, Contributions to Herpetology, Herpetological Circulars, Herpetological Conservation*, and the *Catalogue of American Amphibians and Reptiles* (see below for CAAR details). SSAR members receive prepublication discounts on all *Facsimiles* and *Circulars* and on volumes in the *Contributions* and *Herpetological Conservation* series. A complete pricelist of Society publications is available at: http://www.ssarbooks.com/.

CATALOGUE OF AMERICAN AMPHIBIANS AND REPTILES

The ***Catalogue*** consists of loose-leaf accounts of taxa prepared by specialists, including synonymy, definition, description, distribution map, and comprehensive list of literature for each taxon. Covers amphibians and reptiles of the entire Western Hemisphere. Available for purchase from the SSAR Bookstore (http://www.ssarbooks.com/). Use the prices below to order back issues.

COMPLETE SET: NUMBERS 1–880	check website below for current pricing
INDEX TO ACCOUNTS 1–400: Cross-referenced, 64 pages	$6
INDEX TO ACCOUNTS 401–600: Cross-referenced, 32 pages	$6
SYSTEMATIC TABS (Ten tabs to fit binder: "Class Amphibia," "Order Caudata," etc.)	$6
IMPRINTED POST BINDER (Note: one binder holds about 200 accounts)	$35
INCOMPLETE SET: NUMBERS 1–190	$75
191–410	$85
411–840	$320

To order: make checks payable to "SSAR" and mail to Breck Bartholomew, SSAR Publications Secretary, P.O. Box 58517, Salt Lake City, Utah 84158, USA (fax 801/453-0489). e-mail: ssar@herplit.com. Online orders at: http://www.ssarbooks.com/.

SOCIETY FOR THE STUDY OF AMPHIBIANS AND REPTILES

www.ssarherps.org

The Society for the Study of Amphibians and Reptiles, the largest international herpetological society, is a not-for-profit organization established to advance research, conservation, and education concerning amphibians and reptiles. Founded in 1958, SSAR is widely recognized today as having the most diverse society-sponsored program of services and publications for herpetologists. Membership is open to anyone with an interest in herpetology—professionals and serious amateurs alike—who wish to join with us to advance the goals of the Society.

All members of the SSAR are entitled to vote by mail ballot for Society officers, which allows overseas members to participate in determining the Society's activities; also, many international members attend the annual meetings and serve on editorial boards and committees.

All members and institutions receive the Society's primary technical publication, the *Journal of Herpetology*, and its news-journal, *Herpetological Review*, both are published four times per year. Members also receive pre-publication discounts on other Society publications, which are advertised in *Herpetological Review*.

To join SSAR or to renew your membership, please visit the secure online ZenScientist website via this link:

http://www.ssarherps.org/pages/membership.php

Future Annual Meetings
2011 — Minneapolis, Minnesota, 6–11 July (with ASIH, HL)
2012 — Vancouver, British Columbia, 8–14 August (with ASIH, HL)
2013 — Albuquerque, New Mexico, dates to be determined

A VISION FOR SSAR'S FUTURE

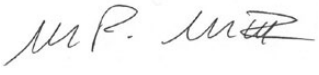
PHOTO BY D. G. MULCAHY

Our society was founded on the ethic of inclusivity and a broad vision for what it means to study and appreciate amphibians and reptiles. These important values are evident in our diverse activities, publications, grants, and awards. Professional societies generally are experiencing declining memberships, but SSAR impressively is holding steady. Although our membership number is a bit lower than at our peak in the mid 1990s, we do remain the largest academic herpetological society in the world.

But this is no time for complacency in our mission or our purpose. The world has changed significantly since our beginnings in 1958, and SSAR must adapt accordingly. The internet has changed the playing field of every aspect of society; amphibians and reptiles, quite incredibly, have became popular as pets; and their global conservation needs have never been more imperative. SSAR must keep pace if we are to continue to advance our constitutionally-prescribed missions of research, education, and conservation. **A timely upgrade of SSAR is in order and is well underway.**

The brainstorms for our new programs took place, like many great ideas do, in the lunchrooms, barrooms, and hallways at the times of our annual meetings. Members suggested that an upgrade was in order and Immediate Past-President Brian Crother directed the energy of an enthusiastic group of members to form a new **Long Range Planning Committee (LRPC)**. SSAR cofounder Kraig Adler chairs the committee, which includes Breck Bartholomew, Rafe Brown, Indraneil Das, Tim Halliday, Robert Hansen, Kristine Kaiser, Roy McDiarmid, James Murphy, Erin Muths, Ann Paterson, and Marion Preest. This group includes three former society presidents, key officers and editors, overseas members, and it represents the great diversity of our membership. In concert with the efforts of the LPRC is a newly launched **Membership Committee (MC)**, chaired by Ann Paterson and including David Bradford, Jason Brock, Marina Gerson, Kristine Kaiser, Wulf Schleip, and Andy Snider. These teams already have invested considerable time toward re-inventing SSAR and it will be rewarding to implement their visions.

Together, the LRPC and MC are directed to modernize SSAR and make it known and attractive to the broadest diversity of future members worldwide. Everything for which SSAR is already known will remain but be improved and new programs and products will be added to benefit our members. Chief among these will be significant updates to our two quarterly serials, with full color becoming standard. **We will also be generally expanding the internet presence of the society.** Expansion requires resources, and the Board of Directors is committed to careful financial stewardship.



The first noticeable change for SSAR is in your hands now—**a wonderful facelift for our workhorse news-journal, *Herpetological Review*.** Recommended by the LRPC and approved by the Board of Directors, our new look follows conceptually the vision that Editor Robert Hansen has brought to *HR* since 1991. Bob's dramatic transformation of *HR* has been astounding, and he further details more upgrades in an accompanying article. Spectacular color images were brought to the cover of the journal in 1995, and more recently to the internal pages thanks to generous financial support from The Thomas Beauvais Fund. The addition of color improved *HR*, and we are now committed to it. Color imagery makes publication more attractive to a broader membership, but this is much more than mere cosmetics. Coloration is an important feature in the lives of our study animals and we can best advance our understanding of their biology—for example, in the section "Natural History Notes"—if we illustrate their full colors.

As SSAR modernizes, our initial focus on *HR* is appropriate because it really represents our core value of inclusivity. Our news-journal is unique among all herpetological publications and really does offer "something for everyone" with an interest in amphibians and reptiles. New additions to *HR* will aim to make it more international in scope and coverage; to make it more attractive to a broader array of herpetological enthusiasts; and to more closely link the increasingly intertwined fields of research and conservation. **A new membership category—Associate Member—**which will receive *HR* only, is being introduced at an attractive price, to entice new members, especially younger ones, to see what SSAR is all about. Watch for the formal announcement to appear in a future issue of *HR*.

SSAR is a broad-based organization with traditions of excellence in research, conservation, and education. Our primary research publication, *Journal of Herpetology*, was named last year as one of the "100 Most Influential Journals in the Past 100 Years in Biology and Medicine" by the Special Libraries Association. **Our *Journal* is now introducing a new "Perspectives" department**, featuring invited papers by leading senior authorities on special topics of interest to herpetologists. The *Journal* will also be including a larger number of color images on its pages. SSAR publishes a remarkable array of top-tier publications that appeal to every level of interest in herpetology. Our 700-page, color-illustrated book, **"Snakes of Honduras" by James R. McCranie, was issued just last month.** (To purchase, see the ad on last page of the December 2010 issue of *HR*.)

Most importantly, SSAR remains true to its founding goals: an inclusive organization that welcomes and encourages persons at all levels to join our society; attend our annual meetings; publish in our journals and series; and generally network to promote the study and appreciation of amphibians and reptiles. As these creatures become increasingly popular in the public's perception, and more frequently featured in the major media, we need to expand our society to do the research, educate the public and schoolchildren, and ensure their conservation. SSAR exists to lead research and conservation, bring herpetology to the people, and open its doors to a diverse membership.

We earnestly solicit your advice on ways that we can better serve the membership and advance the goals of the society and of herpetology as a discipline. You may contact any of the relevant officers and editors (see the inside front cover of this issue) or by writing to me directly at jmendelson@zooatlanta.org.

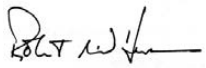
Joseph R. Mendelson III, President

CHANGES FOR *HERPETOLOGICAL REVIEW*

With this issue, we unveil a new look for *Herpetological Review*, featuring full color throughout and a new layout. Additionally, during 2011 we will introduce several content changes.

PHOTO BY BRAD ALEXANDER

- A new section, "**Conservation**," will debut later this year, managed by Section Editor Priya Nanjappa. The goal is to showcase innovative conservation projects, partnerships, and success stories to better bridge the gaps among science, management, and policy.
- A new "**National & Regional Organizations**" section will highlight the activities of national, regional, and taxon-focused organizations and societies, whether amateur or professional. This section will be international in scope.
- An "**Institutional Profiles**" section will feature articles about people and programs associated with herpetology and herpetological research at a variety of types of institutions. As these are published, individual articles will be archived on the SSAR website to serve as a reference for prospective students, or persons planning research travels.
- Our "**Herpetoculture**" section (renamed from "Herpetological Husbandry") will broaden its coverage to include publication of short notes based on captive observations, somewhat analogous to our Natural History Notes (the latter section generally excludes observations based on captive animals). This expansion is made in recognition of the volume of valuable observational data and husbandry knowledge—often developed by amateur herpetologists and herpetoculturists—derived from work with captive amphibians and reptiles. Refer to the note immediately following for details.



Additional information about these new content areas, including how to submit manuscripts, can be found on the SSAR website: http://www.ssarherps.org/pages/HRinfo.php

Other initiatives are in the developmental stages. One of these—"**For Students**"— will focus on gathering information resources of particular interest to students. These will include an up-to-date list of universities that teach herpetology courses, as well as those offering Masters and PhD programs. Job openings, grant opportunities, research requests, internships, news bulletins, and more will be posted in a special section on the SSAR website. We welcome the active participation of student members in the formulation of this project.

To encourage SSAR membership for those who publish in *HR*, each primary or corresponding author who is a current SSAR member will receive a **pdf free of charge** of his/her article, note, or review. Authors who are not SSAR members will still have an opportunity to order reprints (paper or pdf) as before.

We hope our readers enjoy these changes. To offer feedback, please contact us by email (HerpReview@gmail.com) or find us on Facebook ("Herp Review").

Finally, a new year brings changes to our editorial team. **Priya Nanjappa** (USA), **Félix Cruz** (Argentina), **Wulf Schleip** (Germany), and **Jodi Rowley** (Australia) are coming aboard as Section or Associate Editors. **Margaret Gunzburger**, **Meredith Mahoney**, and **Robert Reed** are stepping down as Associate Editors; their service to the herpetological community is greatly appreciated.

Robert W. Hansen, Editor

"HERPETOCULTURE" SECTION TO EXPAND

Along with a new name, our "**Herpetoculture**" section is being redefined and expanded to accommodate a broader range of topical content. This section offers a publication outlet for manuscripts involving amphibians and reptiles in a captive environment—**public or private**. Subjects appropriate for this section include, but are not restricted to, the following:

- *Novel techniques for maintenance and reproduction of live herpetofauna*
- *Genetic management of captive populations*
- *Legal issues in herpetoculture and animal trade: laws, regulations, permits*
- *Reviews of tools, equipment, technology, enclosures, etc.*
- *Safety protocols for working with dangerous species*
- *Policies and procedures related to preventing transmission of pathogens*

Manuscripts that deal exclusively with veterinary medical subjects generally are not appropriate for this section, but consult with Section Editor if in doubt.

Manuscripts, ideas, or questions should be directed to the Herpetological Husbandry Section Editors: **Brad Lock** (block@zooatlanta.org) or **Wulf Schleip** (wschleip@leiopython.de). All manuscripts will undergo external peer review. For detailed instructions on manuscript preparation, please consult the SSAR web page at: http://www.ssarherps.org/pages/HRinfo.php. When reporting on captive held animals, please also consider the Guidelines for Use of Live Amphibians and Reptiles in Field Research, accessible at: http://www.ssarherps.org/pages/HRinfo.php

For authors whose native language is not English and who might require assistance with manuscript preparation, we invite you to consult SSAR's Presubmission Manuscript Review service: http://www.ssarherps.org/page/presub.php

In addition to conventional manuscripts, we will also publish **brief notes based on limited observations of captive animals**. These can be considered analogous to Natural History Notes and should be formatted the same way. Color figures should be supplied as separate files. Subject matter examples include:

- *Courtship and breeding*
- *Behavior (activity patterns, agonistic behavior, etc.)*
- *Clutch / litter size*
- *Gestation / incubation*
- *Growth*
- *Age at first reproduction*
- *Fertility*
- *Longevity*
- *Feeding preferences / techniques*
- *Thermal biology*

Contributions are welcome from all persons who work with captive amphibians and reptiles, including zoo biologists, private herpetoculturists, and institutional professionals.

ABOUT OUR COVER: *ECNOMIOHYLA RABBORUM*

This large species of fringe-limbed treefrog was first discovered near El Valle de Antón, Coclé, Panama in 2005, as collections were being made ahead of the predicted arrival of the pathogenic amphibian chytrid fungus *Batrachochytrium dendrobatidis*; that prediction was based on the arrival and epidemic in the environs of El Copé just to the east (Lips et al. 2006. PNAS 103:3165–3170). The species was described in 2008 by Mendelson et al. (Journal of Herpetology 42:750–759), being named in honor of herpetologists and conservationists George and Mary Rabb. The species is characterized by substantial webbing on the feet, large discs at the ends of the digits, and scalloped fringes of skin on the outer margins of the forearms and the feet. There are conspicuous humeral spines in the males overlain by keratinized cutaneous spicules. Presumably these play a role during amplexus.

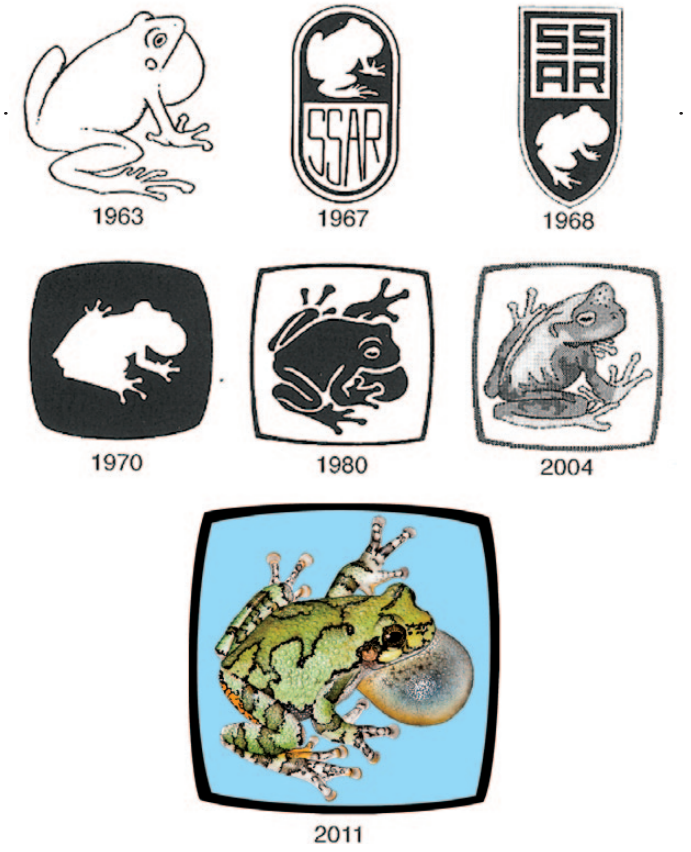
As in the other species of *Ecnomiohyla* that have been observed, this species lives in the forest canopy, and, when threatened, shows a remarkable behavior of leaping from the treetops and using its outstretched limbs and large, webbed hands and feet to glide and orient during its descent. Individuals have been seen to leap from heights of up to nine meters and land safely on the ground. Eggs numbering 60–200 are deposited in water-filled tree holes of various sorts. The tadpoles are large and it may appear that there is more biomass of larvae than actual water in the tree hole. Males appear to defend territories, including a particular tree hole, including production of vocal calls seemingly unrelated to breeding which takes place in the summer rainy season. After laying eggs, the female departs, but the male remains to attend eggs and tadpoles. Attendant males proceed to show a behavior that we interpreted to represent direct paternal nutrition of the larvae (which is otherwise undocumented in amphibians). The male backs his body into the water and writhing mass of tadpoles, which then proceed to forage vigorously on his skin—presumably rasping epidermal cells as a form of nutrition, as is known to occur in some female caecilians (Kupfer et al. 2006. Nature 440:926–929).

Ecnomiohyla rabborum is listed as Critically Endangered on the IUCN Red List, with that designation being based on its small range (known only from the immediate vicinity of the type locality) and its presumed susceptibility to chytridiomycosis. The predicted epidemic of chytridiomycosis in this area took place in 2006. This frog was last heard (but not seen) in the wild in 2007 and is now known from only two living specimens (both males) located at two facilities in Atlanta. This scenario is recounted in an essay by Joe Mendelson elsewhere in this issue.

Brad Wilson recorded our cover image using a Canon 1ds Mark iii DSLR with a Canon 100mm f2.8 macro lens, mounted on a Gitzo Explorer tripod with G1376 off-center ball head. Lighting was accomplished using two off-camera 580EX flash units and a Photoflex light dome. The image was shot at ISO 400, f10, at 1/20 sec, and recorded in RAW, with post-processing in Adobe Photoshop CS4. Wilson is a veterinarian in Atlanta, Georgia and a graduate of The University of Georgia College of Veterinary Medicine 1994. Brad became the consulting veterinarian for the Atlanta Botanical Garden in 1995 and together with Ron Gagliardo instituted the ABG amphibian collections. Brad has provided many volunteer hours as a consultant on amphibian conservation projects in Costa Rica, Panama, Ecuador, Peru, and Malaysia since 2005. He is currently the co-owner of two private small animal practices in north metro Atlanta. He also serves as a principal consulting veterinarian with Amphibian Ark, http://www.amphibianark.org/.

PHOTO BY RICK MCCARTHY

Brad's photographic interests include all things natural history and his amphibian photographs have been published internationally for numerous conservation organizations. His most current photography project is assisting with the cataloguing and field photography of all native orchid species in Georgia. His photographs may be viewed at:



http://www.flickr.com/photos/frogdr/collections/

SSAR BUSINESS

Colorized SSAR Logo

With the inauguration of an all-color *Herpetological Review*, it is appropriate to introduce a colored version of the society's official logo. The current logo, which has become known internationally as the most recognizable symbol of SSAR, has now been rendered in watercolors by David M. Dennis, the noted wildlife artist and nature photographer. He was one of the society's founders in 1958. The new image is based on a specimen of the Gray Treefrog (*Hyla versicolor*) collected by Mr. Dennis just east of Columbus, Ohio, in 1978.

The first version of the society's logo appeared in 1963 on the cover of the *Journal of The Ohio Herpetological Society*, the predecessor serial to today's award-winning *Journal of Herpetology*, which began in 1968. The logo depicts a frog in the act of communicating, a function that is the primary role of any scientific society. The original logo underwent many modifications in the 1960s and 1970s, most of them drafted by Mr. Dennis. The current, simpler version by Mr. Dennis was introduced in 1980. It has generally been printed in black, white, or light blue, the society's official colors. (The 2004 color version has been used on the SSAR website.)

SSAR Election Results

Results of the 2010 SSAR election are as follows:

President-Elect: ..... Robert Aldridge
Treasurer: .....Kirsten Nicholson
Secretary: ..... Marion Preest
Board Members (Regular): ..... Tiffany Doan, Carol Spencer
Board Member (Conservation): ..... Jennifer Pramuk
Board Member (Regional Society): ..... Travis LaDuc

Thank you to all of the nominees who agreed to stand for positions and to Dan Noble (Elector Officer).

—Marion Preest, SSAR Secretary

SSAR Henri Seibert Awards for 2011

The Henri Seibert Awards were initiated in 1992 to provide recognition for the best student papers presented at the annual meeting of the SSAR. To be eligible, the presented paper must be the result of research by the individual making the presentation. The research must have been conducted while the student was enrolled in either an undergraduate or graduate degree program. Please refer to *Herpetological Review* 28(4):175 and the SSAR website (http://www.ssarherps.org/pages/seibert.php) for recommendations to students entering the Henri Seibert Competition. Students entering the competition must be members of SSAR. The presentations will be judged by the SSAR student prize committee. One Henri Seibert Award of US $200 may be given in each of the following four categories: **Systematics/Evolution, Ecology, Physiology/Morphology**, and **Conservation**. Students may win a Henri Seibert award only one time. Please indicate the appropriate category for which you are applying on the abstract submission form. Announcement of winners will be made at the SSAR Business Meeting. All participants should be present at the business meeting. Contact Rafe Brown (e-mail: rafe@ku.edu) for further information.

SSAR Poster Awards for 2011

This is the inaugural year for the SSAR Poster Award. The SSAR Poster Awards will provide recognition for the best student posters presented at the annual meeting of the SSAR. To be eligible, the presented poster must be the result of research conducted by the individual making the presentation. The research must have been conducted while the student was enrolled in either an undergraduate or graduate degree program. Students entering the competition must be members of SSAR. The presentations will be judged by the SSAR student prize

committee. One SSAR Poster Award of US $100 (plus a book gift from the University of California Press) may be given in each of the following four categories:

- Evolution, Genetics, & Systematics
- Ecology, Natural History, Distribution, & Behavior;
- Physiology & Morphology
- Conservation & Management

The SSAR Poster Award will be judged by the following criteria:

- Quality of Research
- Quality of the Visual Display of the Research
- Professionalism and Confidence of the Presenter

Recommendations to Students Entering the SSAR Poster Competition

The SSAR Poster Award will be presented for the first time in Minneapolis at the 2011 Joint Meeting. The SSAR Board of Directors wishes to recognize that poster presentations are an important part of the annual Joint Meeting event and that they are an important component of the graduate and undergraduate experience. The presentation of some research projects is better suited to a poster session, which allows much greater communication between the presenter and the audience. The following recommendations are intended to aid students in improving the quality of their poster presentations. The criteria presented below are applicable to any poster given at a scientific meeting.

Preparing the Presentation

A. The Poster

- More so than an oral presentation, a poster needs to visually draw in the audience. When hundreds of posters are up at the same time, one's poster needs to stand out to be noticed.
- Organization is key—a cluttered poster that is hard to read will not keep the attention of the audience.
- Use large fonts: at least 28–36 size font for the smallest words; approximately 90 size for the title.
- Use *sans serif* fonts such as Arial, Helvetica, and Calibri, which are easy to read from a distance.
- Use as many figures as possible, including graphs and photographs, to display your data.
- Use color to your advantage, but do not make it overwhelming. No one wants to look at a black-and-white poster, but too much color can be distracting.
- Do not include paragraphs on your poster (no one wants to stand there and read them). Bullet points or short sentences are much easier to read.

B. Oral Presentation

- Prepare a short explanation to your poster so that viewers do not have to read everything.
- Anticipate questions that your audience might have.
- Be prepared to discuss further research that you may later perform based on the results from the project about which you are presenting.
- Remember that other scientists have stopped at your poster because they are interested in your research. Relax and enjoy the experience of "talking shop" with other scientists who share similar interests.

Describing your Research

A. Design

- Present your research in a larger context by addressing previous studies (choose 1 or 2 to make your point). Relate your data to the knowledge of your field.
- Clearly state your hypothesis(es) and/or objectives up front.
- Flag techniques that are original to your study (i.e., this study is the first to address this question or to use this technique).

B. Summary of Results

- Present your results clearly. Tables with N and P values are fine (but not necessary) if they are readable. Always indicate your sample sizes.
- Indicate the importance of your results. How do they relate to previous studies? Biology in general?

C. Importance of Study

- An abstract, summary, or conclusions section of your poster is helpful in tying together many results.
- State the importance of your study and how your research has added to knowledge of the subject presented. Are your results generally applicable to larger biological questions?

Students may only win the award one time. Please indicate the appropriate category for which you are applying on the abstract submission form. Announcement of winners will be made at the SSAR Business Meeting. All participants should be present at the business meeting. Contact Tiffany Doan (e-mail: DoanTiM@ccsu.edu) for further information.

NEWSNOTES

Kansas Herpetological Society Annual Meeting

The Kansas Herpetological Society held its 37th Annual Meeting at the Topeka Zoo in Topeka, Kansas, on 6–7 November 2010. Over 100 participants attended scientific paper sessions presented by scientists and students from across the nation.

Jodie Hearlson, student at Emporia State University, received the 2010 Howard K. Gloyd/Edward H. Taylor Scholarship, honoring the memory of two great biologists with strong ties to Kansas.The 2010 Alan H. Kamb Grant for Research on Kansas Snakes was made to Prashant Deshmukh, Emporia State University. George Pisani, Kansas Biological Survey, was

the 13th recipient of "The Suzanne L. & Joseph T. Collins Award for Excellence in Kansas Herpetology." Katie Talbott, Fort Hays State University, was presented with the George Toland Award for the best student paper given at the meeting. Travis Taggart, Sternberg Museum of Natural History, received the Bronze Salamander Award for his years of service to KHS. The inaugural "Henry S. Fitch-Dwight R. Platt Award for Excellence in Field Herpetology" was made to Stanley Roth, Kansas Biological Survey.

The J. Larry Landers Student Research Grant

The J. Larry Landers Student Research Grant is a Gopher Tortoise Council competitive grant program for undergraduate and graduate college students. Proposals can address research concerning Gopher Tortoise biology or any other relevant aspect of upland habitat conservation and management. The amount of the award is variable, but projects up to US $2,000 have been awarded.

The proposal should be limited to four pages in length and should include a description of the project, a concise budget, and a brief resume of the student. Submissions via e-mail as text files are preferred.

This is an excellent opportunity for undergraduate and graduate students to access funding for their projects. The deadline for grant proposals is 15 September 2011. Please send submissions to: Bob Herrington, Chairperson, Research Advisory Committee, Department of Biology, Georgia Southwestern State University, Americus, Georgia 31709, USA; e-mail: bherring@canes.gsw.edu.

MEETINGS

Meetings Calendar

Meeting announcement information should be sent directly to the Editor (HerpReview@gmail.com) well in advance of the event.

23–27 May 2011—Second Mediterranean Congress of Herpetology, Marrakech, Morocco. Information: http://www.ucam.ac.ma/cm2

19–22 June 2011—Sixth Hellbender Symposium, Ligoneer, Pennsylvania, USA. Information: mcmillan@buffalostate.edu

6–11 July 2011—Joint Meeting of Ichthyologists and Herpetologists (ASIH / HL / SSAR), Minneapolis, Minnesota, USA. Information: http://www.dce.k-state.edu/conf/jointmeeting/

17–22 July 2011—IX Congresso Latinoamericano de Herpetologia, Curitiba, Brazil. Information: http://clah2011esp.blogspot.com/

20–23 July 2011—Biology of the Rattlesnakes Symposium, Tucson, Arizona, USA. Information: http://www.williamkhayes.com/rattlesnakes/

27–30 July 2011—34th International Herpetological Symposium, Fort Worth, Texas, USA. Information: http://www.kingsnake.com/ihs/

8–14 August 2012—World Congress of Herpetology 7, Vancouver, British Columbia, Canada (together with SSAR, HL, ASIH). Information: http://www.worldcongressofherpetology.org/

2–7 September 2012—4th International Zoological Congress (IZC), Mount Carmel Campus, University of Haifa, Haifa, Israel. To receive the first and subsequent meeting announcements, contact the organizers at: izc2012@sci.haifa.ac.il.

CURRENT RESEARCH

The purpose of Current Research is to present brief summaries and citations for selected papers from journals other than those published by the American Society of Ichthyologists and Herpetologists, The Herpetologists' League, and the Society for the Study of Amphibians and Reptiles. Limited space prohibits comprehensive coverage of the literature, but an effort will be made to cover a variety of taxa and topics. To ensure that the coverage is as broad and current as possible, authors are invited to send reprints to the Current Research section editors, Joshua Hale or Ben Lowe; e-mail addresses may be found on the inside front cover.

A listing of current contents of various herpetological journals and other publications is available online. Go to: http://www.herplit.com and click on "Current Herpetological Contents."

Enigmatic New World Snake Found to Represent Ancient Lineage

A number of studies conducted in the first decade of the 21st century have helped shed light on the evolutionary relationships

of snakes and alleviate the taxonomic confusion that reigned through the 20th century. The authors of this paper present the results from the most inclusive molecular phylogenetic analysis to date focusing on advanced snakes (Colubroidea), featuring 299 genera and 761 species. An attempt was made to acquire data for five genes (two nuclear and three mitochondrial) for all taxa; however a "supermatrix" approach was employed, whereby new and previously published sequence data is combined into a single dataset and analyzed together, despite many taxa missing data for some or even most of the genes. The authors posit that previous studies have supported the use of this method. The recovered phylogeny largely corroborates other recent studies. In particular, a number of lineages once regarded as members of the family Colubridae are either more closely related to Elapidae (Lamprophiidae, Homalopsidae) or occupy a basal position within Colubroidea (Pareatidae, Xenodermatidae). The most exciting novel discovery of this analysis is the finding that the Skinkeater (*Scaphiodontophis annulatus*), a little-known snake of the New World tropics, is the sole living member (at least of sampled species) of an ancient, heretofore unknown lineage in the family Colubridae (comparable in divergence to colubrid lineages given the rank of subfamily). Long thought to belong to the subfamily Colubrinae, the phylogenetic distinctiveness of this taxon with respect to other colubrine snakes is consistent with early immunological data and its suite of unique, derived characters such as hinged teeth and advanced intervertebral tail autotomy. In order to maintain the monophyly of Colubrinae, the authors propose the erection of the subfamily Scaphiodontophiinae to accommodate *S. annulatus*, rather than placing Grayiinae and Calamariinae in synonymy with Colubrinae. Future studies should include representatives of other enigmatic taxa such as *Sibynophis, Enulius*, and *Urotheca* (all of which have been hypothesized to be allied with *Scaphiodontophis*).

Pyron, R. A., F. T. Burbrink, G. R. Colli, A. N. Montes de Oca, L. J. Vitt, C. A. Kuczynski, and J. J. Wiens. 2010. The phylogeny of advanced snakes (Colubroidea), with discovery of a new subfamily and comparison of support methods for likelihood trees. Molecular Phylogenetics and Evolution (in press). doi:10.1016/j.ympev.2010.11.006.

Caribbean Lizards Solve the Problem of Signaling Amid Noise in Different Ways

Successful intraspecific communication amid distracting background noise (be it auditory, visual, or chemical) is a problem experienced by many organisms. Interestingly, different lineages have sometimes arrived at different solutions to the same problem; these situations are valuable in that they shed light on basic evolutionary processes. The authors of this paper examined communication in *Anolis* communities occurring on the Caribbean islands of Jamaica and Puerto Rico. This system provides an opportunity to study the evolution of signaling strategy, as both islands have species specializing on the same habitats (edge, open woodland, closed-canopy woodland) despite each island's *Anolis* species assemblage being monophyletic. Representatives of eight *Anolis* species (four on each island) were video recorded while engaged in headbob and dewlap-extension displays. Furthermore, background "noise" (wind-blown vegetation) level was simultaneously evaluated. The findings of previous studies were corroborated in that Jamaican *Anolis* engage in significantly more rapid displays (relative to their Puerto Rican counterparts), which have been hypothesized to be effective in noisy situations. Furthermore, multilevel regression analyses simultaneously examining timing of display (relative to timing of noise), lizard species, and island species group revealed Puerto Rican *Anolis* were significantly more likely to display during periods of reduced noise than Jamaican *Anolis*. As the variation in display strategy was principally between islands and not between ecological niches, this study finds strong evidence for the divergent signaling strategies being a consequence of the two communities having different evolutionary starting points.

Ord, T. J., G. K. Charles, and R. K. Hofer. 2011. The evolution of alternative adaptive strategies for effective communication in noisy environments. American Naturalist 177:54-64.

Unisexual *Ambystoma* of Ancient Origin

Because of a limited ability to evolve stemming from the lack of genetic recombination, evolutionary theory predicts asexual lineages should be short lived. However, it has been hypothesized that unisexual *Ambystoma* (Ambystomatidae) salamanders of eastern North America may be an exception to the rule. Unisexual *Ambystoma* constitute a genetically and reproductively complex group featuring nuclear genetic material from five sexual species but comprise a monophyletic mitochondrial group nested within the sexual species *Ambystoma barbouri*. Despite early studies concluding that the unisexual *Ambystoma* lineage originated as the result of an ancient hybridization event (with *A. barbouri* as the maternal species), a recent study using the mitochondrial (mt) gene cytochrome b (cyt-b) deduced that unisexual *Ambystoma* are genetically indistinguishable from some *A. barbouri*, implying that they are instead of recent origin. To resolve this conflict, the authors of this study generated complete mt genome sequences for two *A. barbouri* (one of which was found to be indistinguishable from unisexual *Ambystoma* in the previous study), and one unisexual *Ambystoma* (only one was necessary as previous studies have found unisexual *Ambystoma* to lack mt variation). Additionally, cyt-b sequences were produced using the protocol employed

in the previous study. The mt genome of the unisexual *Ambystoma* was found to be genetically distinct from both *A. barbouri*. An analysis resulting in a time-calibrated phylogeny reveals the asexual *Ambystoma-A. barbouri* split occurred roughly five million years ago. Interestingly, close inspection of the *A. barbouri* cyt-b gene recovered using the protocol of the previous study revealed that the sequence had several heterozygous sites; as organisms possess only a single copy of mt genes, this suggests that what is actually being amplified and sequenced is a nuclear "pseudogene" (a gene fragment that has found its way into the nuclear genome and is presumably functionless, "junk DNA"). These findings strongly support the ancient origin of unisexual *Ambystoma*; indeed, they may be the oldest unisexual vertebrate lineage known to science.

Bi, K., and J. P. Bogart. 2010. Time and time again: unisexual salamanders (genus *Ambystoma*) are the oldest unisexual vertebrates. BMC Evolutionary Biology 10:238.

Frogs Can Excrete Body Cavity Objects Via Their Bladders

Despite being the model organism for classroom anatomical study for nearly a century, we are still learning new aspects of anuran anatomy. The authors of this paper describe a heretofore unknown ability of frogs—the capacity to pass objects in their body cavity through the wall of their bladder, allowing them to be excreted with their urine. This ability was serendipitously discovered as the researchers attempted to remove radio transmitters from several frogs at the terminus of a study, only to find many of the transmitters had moved into the frog's bladders. Finding evidence of this phenomenon in three species of Australian treefrogs (Hylidae: Pelodryadinae) led them to ask if this ability was more widespread among anurans. To answer this question, and to better document this ability, they surgically implanted small beads into the body cavities of 36 toads (Bufonidae: *Bufo* [*Rhinella*] *marinus*) and five treefrogs (Hylidae: *Litoria caerulea*). Thirty-one of the *B. marinus* were dissected over the course of several days to document the progression of bead sequestration; the remaining frogs were maintained alive until the end of the study (45 days). At the end of the study, all *L. caerulea* had expelled their beads (average = 19 days) while only one of the five *B. marinus* had done so. However, upon dissection, it was revealed that the remaining four *B. marinus* possessed the beads within their bladders. Investigation of the *B. marinus* dissected through the course of the studied that envelopment of the beads by the bladder began as early as day two and all beads were enveloped by day seven. While other vertebrates have shown the ability to expel body cavity objects through either the intestines or the skin, this finding marks the first documentation the use of the bladder in expelling objects. Finally, the authors posit that this ability may be an adaptation aiding the removal of objects forced into the body cavity by the force frequently exerted upon the frog's ventrum when landing following a jump.

Tracy, C. R., K. A. Christian, L. J. McArthur, and C. M. Gienger. 2010. Removing the rubbish: frogs eliminate foreign objects from the body cavity through the bladder. Biology Letters (*in press*). doi: 10.1098/rsbl.2010.0877.

Fossil Reptiles Reveal Insights into Venom Delivery Evolution

Several dental morphologies aiding in venom delivery exist among extant reptiles, from the open grooves of Helodermatidae and some Colubroidea (opisthoglyphous condition) to the enclosed canals of Elapidae and Viperidae (proteroglyphous and solenoglyphous conditions, respectively). Studies of the development of replacement fangs in extant snakes have revealed the venom tube begins as a basal groove which elongates, narrows, and finally folds over, forming an enclosed tube. Whether this represents a viable hypothesis for the evolution of hollow fangs has remained unknown. The authors of this study describe *Uatchitodon schneideri*, a new species of Triassic archosauriform (crocodile-looking and early diverging members of the clade containing crocodilians, dinosaurs, and birds) from North Carolina, USA bearing twin (medial and lateral) tubes along the length of each tooth. This species appears to be derived from a previously-described species, *Uatchitodon kroehleri*, also known from deposits in eastern USA. As *U. kroehleri* exhibits opistoglyphous teeth with paired grooves either on the proximal end or along the whole length, the tooth of *U. schneideri* represents the culmination of the evolution of the proteroglyphous condition. Indeed, close scrutiny of some *U. schneideri* teeth reveal a faint seam, signifying where the tube was ultimately closed. The authors consider other potential uses for the grooves and tubes and systematically rule out any use other than venom delivery. They also highlight the uncanny similarity of this progression to the development of replacement teeth in snakes. These findings demonstrate one potential pathway for the evolution of hollow fangs in reptiles.

Terrestrial Chameleon Locomotion Assisted by Tail

Aided by prehensile tails and zygodactyly, arboreal members of the family Chamaeleonidae are the masters of their environment. Do diminutive, terrestrial chameleons (which represent as much as 30% of chameleon species) also possess distinctive locomotor adaptations? The use of the tail during locomotion has been documented in species of *Brookesia*; however, whether the tail is being used for balance or propulsion has remained unknown. To shed light on this behavior, the authors of this study recorded video of two species of *Brookesia* (*B. thieli* and *B. superciliaris*) moving across narrow (1.38 mm diameter wire) and flat surfaces. Furthermore, they generated x-ray microtomographic images of *B. thieli* and two arboreal iguanians, *Calumma tigris* and *Anolis carolinensis*, paying particular attention to tail and inner ear morphology. Video footage confirmed the use of the tail in locomotion. Specifically, the dorsal surface of the tip of the tail is placed in the substrate when walking on flat surfaces (twice every four foot movements); very narrow surfaces elicit the same tail movements, yet the tip does not make contact with the surface. A comparison of body position when the tail is, and is not, in contact with substrate suggests the tail is only serving as a balance and not propulsion. In support of this hypothesis, most of the tail musculature is primarily devoted to flexion, with much less muscle tissue that would provide extension. Additionally, unlike arboreal chameleons, only the distal caudal vertebrae are adapted for movement, with the proximal vertebrae possessing movement-suppressing dorsal shields. Finally, the inner ear of *B. thieli* appears to be an adaptation to terrestrial movement, as the horizontal canal is flattened vertically (and therefore function optimally when the animal is on a flat surface) relative to the condition seen in *A. carolinensis* and *C. tigris*. This study reveals that the lesser-known terrestrial chameleons also exhibit interesting locomotory adaptations.

The Nuclear Gene "POMC" Fails to Resolve Turtle Placement in Tetrapod Tree

Uncertainty regarding the phylogenetic placement of Testudines persists, as studies continue to emerge presenting evidence for alternative topologies. The most tenable hypotheses are: a) turtles are sister to diapsids, b) turtles are diapsids and sister to archosaurs, and c) turtles are diapsids and sister to lepidosaurs. The authors of this paper conducted a study aiming to help solve this fundamental mystery in the field of herpetology. Hoping to capitalize on this marker's usefulness in resolving other deep nodes in the vertebrate tree of life, they generated POMC (the nuclear gene coding for proopiomelanocortin) sequences for a turtle and a snake, and along with ~35 previously-published vertebrate sequences, conducted several phylogenetic analyses (each using different algorithms, indices of support, partitioning schemes, and/or parameter values). Unfortunately, these analyses failed to recover a well-supported position for Testudines. Despite good indices of clade support throughout the rest of the tree, no analysis confidently resolved the turtle-archosaur-lepidosaur clade. Perhaps the two divergence events leading to these three lineages occurred in quick succession, without the time needed for phylogenetically-informative synapomorphies to accumulate.

Species and Life-stage Differences in Susceptibility to Chytrid in Two Australian Anurans

How frog species vary in susceptibility to the chytrid fungus, and whether larval and recently metamorphosed anurans also exhibit different vulnerabilities to this pathogen are questions important to the effort to avert a global amphibian extinction event. To explore these questions, the authors of this paper exposed both age classes of two species to chytrid fungus and documented their response. They chose to use two sympatric Australian species, a myobatrachid, *Limnodynastes peronii*, and a hylid, *Litoria aurea*. As the latter has undergone recent precipitous population declines (while the former has not) and chytrid is the suspected culprit, the results of this study have conservation implications as well. Captive bred representatives of both species were raised to the tadpole or juvenile stage and exposed to chytrid fungus (except for controls). The condition of the animals was assessed visually daily and the degree of chytrid infection was determined via quantitative PCR two weeks after inoculation and three and six months after metamorphosis. The two species were found to show very different susceptibilities to chytrid, with no infected *L. aurea* surviving to 100 days while *L. peronii* and uninfected *L. aurea* displayed greater than 80% survivorship over the same period. Indeed, pathogen loads significantly decreased in both larval and juvenile *L. peronii* over the experiment. Furthermore, survivorship did not decrease linearly with respect to pathogen load; instead, there appeared to be a threshold concentration, below which survivorship was unaffected and above which survivorship precipitously

declined. Taken together these results suggest a threshold level of chytrid load, above which chytridiomycosis sets in and survivorship plummets; the apparent chytrid immunity exhibited *L. peronii* may be due to its ability to keep chytrid infection levels below this threshold. Despite these considerable species differences, no within-species age-class differences in survivorship where detected, although the threshold level of pathogen concentration was lower for tadpoles. This study presents strong evidence for chytrid being the causal agent responsible for *L. aurea* declines and sheds more light on the relationship between chytrid infection and chytridiomycosis and how susceptibility varies across species and life stages.

Stockwell, M. P., J. Clulow and M. J. Mahony. 2010. Host species determines whether infection load increases beyond disease-causing thresholds following exposure to the amphibian chytrid fungus. Animal Conservation 13 (issue supplement s1): 62–71.

Method of Securing Transmitters in Snakes Prevents Expulsion

Radio telemetry has proven to be a valuable method of collecting data on reptile movements. However, with some organisms (particularly snake species) expulsion of devices placed within the coelomic cavity has been a problem. The authors of this study present some results from a study wherein one possible solution to this problem was employed. For an ecological study of Australian Carpet Pythons (*Morelia spilota*), 46 pythons were implanted with radio transmitters using standard procedures. Of those, half of the snakes received an additional treatment: the attachment of the transmitter to a rib via sutures. The snakes were then released and followed for the remainder of the three year study. Twelve of the 23 animals with unsecured transmitters voided their transmitters while none of the animals with secured transmitters did so. Contrary to what previous investigators have hypothesized, as only three of the expelled transmitters were associated with feces, transmitter expulsions appear to not be solely associated with the passage of food through the intestinal tract. The discovery that this simple technique can prevent the voiding of radio transmitters represents an important innovation for future telemetry studies.

Bryant, G. L., P. Eden, P. de Tores, and K. Warren. 2010. Improved procedure for implanting radiotransmitters in the coelomic cavity of snakes. Australian Veterinary Journal 88:443–448.

Tortoises Learn from Watching Other Tortoises

Although tortoises are solitary animals; it is possible that they learn from watching the actions of other tortoises. To investigate this question, the authors of this study subjected Red-footed Tortoises (*Geochelone carbonaria*) to a simple obstacle course under different conditions. In the control group, four tortoises were allowed repeated opportunities to complete the course and their success rate was documented. Subsequently, these tortoises were subjected to the trial repeatedly until they had learned the lay of the course. In the experimental treatment, four naive tortoises were subjected to several trials wherein they were allowed to observe the trained tortoises complete the course before attempting themselves. Fresh substrate was laid on the course between observation and attempt, eliminating the scent of the trained tortoise. The success rate of the tortoises in both of the treatments was then compared. In twelve trials each, none of tortoises in the control group completed the course; conversely, all tortoises in the experimental group completed the course at lead twice, with two of them completing more than 90% of the time. As this represents a statistically significant difference between the two groups, this finding suggests that tortoises do indeed possess the capacity to learn from observing conspecifics. Perhaps social learning in non-social animals is a more widespread phenomenon than is currently appreciated.

Wilkinson, A., K. Kuenstner, J. Mueller, and L. Huber. 2010. Social learning in a non-social reptile (*Geochelone carbonaria*). Biology Letters 6:614–616.

Amphibian Species Shifting Breeding Time in Response to Climate Change

Pond-breeding amphibian communities frequently exhibit partitioned use of aquatic sites temporally, with only a subset of the species breeding at any one time. However, changes in regional climate could disrupt reproductive patterns and potentially intensify competition between certain species. To determine if changes in amphibian phenology are a concern, the authors of this paper analyzed data collected over thirty years for ten amphibian species. Data was collected from a wetland site on the property of the Savannah River Ecological Laboratory in South Carolina, USA. The site was sampled for reproductive amphibians throughout the year and for each year a median arrival date was calculated. Annual variation in breeding time was tested for correlations with variation in moisture and temperature observed over the course of the study. They found several species for which the timing of reproduction had sig-

nificantly changed over the course of the sampled period. Both autumn breeding amphibians (two salamander species) were breeding later. Additionally, two of the five winter breeding amphibians, an anuran and a salamander were breeding sooner. Finally, six of the ten species were found to have a statistically significant correlation between timing of breeding and at least one of the two climactic variables. Together, these results reveal a significant shift in phenology (15–76 days) for about half of the members of a community in a relatively short period. Pond-breeding amphibians exhibit complex interactions of predation and resource competition and the impact of these changes could be large. As this study also documented significant population declines in six of the species, changes in phenology represent a potential culprit. This work demonstrates that climate-change-induced changes in phenology may bring about cascading effects on amphibian communities.

Todd, B. D., D. E. Scott, J. H. K. Pechmann, and J. W. Gibbons. 2010. Climate change correlates with rapid delays and advancements in reproductive timing in an amphibian community. Proceedings of the Royal Society B (*in press*) doi: 10.1098/rspb.2010.1768.

Male Banded Geckos Successfully Court Females Despite Removal of Testosterone

Males of most vertebrate species rely on testosterone (T) for the development of male sexual characteristics and the coordination of reproductive behaviors. For instance, in the Leopard Gecko (Eublepharidae: *Eublepharis*), it has been shown that the characteristic courtship routine (tail twitching and pheromone deposition) is inhibited in the absence of T. In this study, the authors investigated the role of testosterone in another eublepharid gecko, the Yucatan Banded Gecko, *Coleonyx elegans*. As the *Coleonyx* lineage has lost the courtship routine exhibited by other eublepharids, the authors aimed to determine the effects of T removal on reproductive behavior in non-courting species. Upon sexual maturity, lizards reared from eggs were placed into one of three treatments: castration (male), castration with T supplement (male), female with T supplement, and control (male and female). Animals not receiving T supplement were administered placebo implants. Five weeks following surgery males were subjected to reproductive trials, wherein they were presented with a female (from the control group) and observed for reproductive behavior. Activities were conducted under a red light, observed via closed-circuit television from another room, and were interrupted prior to copulation so the females would remain receptive for subsequent trials. Seven weeks after surgery, females of both treatments were subjected to trials of the same design. At ten weeks post-surgery, two of the castrated males were subjected to another round of trials. Males of all treatments exhibited no difference in reproductive response when presented with receptive females (even ten weeks post-surgery), signifying elevated T levels are not needed for reproductive behavior in *Coleonyx*. Interestingly, this is contrary to what has been determined in studies of other squamates. Additionally, females administered supplementary T exhibited the same response as males when presented with females. The authors argue that these seemingly opposing findings suggest that T is important in the development of normally-functioning males (but not at the moment of reproduction) and that females retain sensitivity to T, causing them to masculinize when it is administered.

Golinski, A., H. John-Alder, and L. Kratochvíl. 2010. Male sexual behavior does not require elevated testosterone in a lizard (*Coleonyx elegans*, Eublepharidae). Hormones and Behavior (*in press*) doi:10.1016/j.yhbeh.2010.11.007.

Art in Herpetology

As space and available material permit, we will occasionally publish examples of historical as well as contemporary herpetological art. An example of this can be seen on page 42 in this issue. We welcome the submission of historical material under the following conditions:

- The work should be copyright-free and be provided as a high-resolution digitized file (consult Editor for specifications).
- Accompanying text should provide information on the subject matter, artist/illustrator, and publication source. Include references as needed to appropriately attribute information from other sources.

Contemporary artists are invited to submit their own work for publication:

- Artist will retain copyright of all submitted material.
- Accompanying text should provide information about technique, media, or other information likely to be of interest, especially to other artists. Source of illustration subject (e.g., scientific name, geographic origin, etc.) should be included.
- Artists are welcome to include contact information (e.g., email address, website location), as well as indicating whether original art or prints are available for sale or if the artist is available for commissioned work.

OBITUARIES

Ernest Anthony Liner 1925–2010

Ernest Anthony Liner was born on 11 February 1925 to Remie Antoine Liner and Leonise Marguerite Arceneaux Liner, who both preceded him in death, and died on 22 September 2010. Both his birth and death took place in Houma, Terrebonne Parish, Louisiana. He was surrounded by family as he peacefully passed at about 10:34 pm in bed at Terrebonne General Hospital. He is survived by one sister, Jeannette Liner Gomez, and by12 nieces and nephews. He was preceded in death by his other sister, Mary Ann Fayette.

It is interesting that Ernie (as he was known to his friends and colleagues) was born and died in the same bayou town in southern Louisiana, because that belies his life. The humble, extremely affable Ernie lived an expansive life and saw much of the world. He was a Pacific theater WWII hero and received two Purple Hearts, two Presidential Unit Citations, and the Asian-Pacific Combat Medal. He attended Southwestern Louisiana Institute (now the University of Louisiana at Lafayette) and Louisiana State University and earned his B.S. degree in Biology in 1951. He worked for a while as a sixth grade teacher and then was hired by Fred Cagle for the Zoology Department at Tulane University in 1952. After three years there he took a pharmaceutical salesman position with E.R. Squibb and Sons, with whom he worked until his retirement in 1987. Ernie was an active member of SSAR, ASIH, HL and the Southwestern Association of Naturalists (who recognized him for his service in 1993) and was a member of 14 societies. He published over 150 papers (including species and subspecies descriptions) and books, including arguably his *pièce de résistance*, the final volume in the acclaimed Biology of the Reptilia series, the 1366 page *Comprehensive Literature of the Reptilia* (Liner 2010). He was in the Marquis Who's Who of America and received an honorary doctorate from the University of Colorado, which impressively was supported by over 125 letters from colleagues around the world. He was of course also famous for his amazing herpetofauna cookbooks, which culminated in his summary volume, *The Culinary Herpetologist*, which has almost 1000 recipes (Liner 2005). Remarkably, Ernie accomplished almost of this while working as a full-time pharmaceutical salesman! As David Chiszar noted about Ernie in Mitchell (2006), "It is possible to have a fairly distinguished career as a hobby." Besides being a world-renowned herpetologist, he was also something of a local celebrity and was often the subject of articles in the local press, most recently in 2009 (Lizards and Frogs and Snakes, Oh My!, Point of Vue, Dec. 2009) and in 2010 (Dangerous Creatures, The Courier, Feb. 28, 2010).

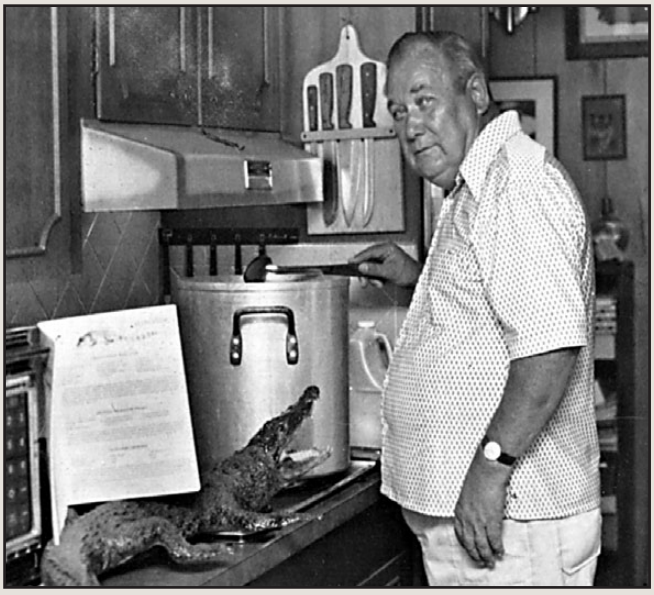

FIG. 1. Ernie is trying out recipes for alligator stew at his home. September 1985. Photo courtesy of *Terrebonne Magazine*.

Right up to his passing, Ernie remained active locally as one of the organizers of a biennial herpetology conference held south of Houma at LUMCON (the Louisiana Universities Marine Consortium) in November. Before each meeting, Ernie preferred to visit LUMCON, rather than just email or telephone, where he would work with the staff to organize the conference details; after the meeting, he would take a gift to the staff members to indicate his appreciation for their friendliness and help. Ernie also took responsibility for updating the conference mailing list; he always managed to know when herpetologists moved into or out of Louisiana--including many of the students throughout the state. For many of the meetings, he cooked a fantastic seafood gumbo for the Saturday night meal. At every conference, he would give each attendee a "ditty bag" of items such as promotional materials about Houma and south Louisiana, and the Mardi Gras beads and cups that many people fondly remember receiving from him at that meeting and others. After each meeting, he would welcome the attendees to visit his house on the way home, where he would share stories, reprints, and occasionally some books from his impressive library. As always, Ernie was fond of sharing items and ideas, and of meeting and renewing friendships with students and more senior herpetologists.

To detail these parts of Ernie's life would require essentially copying an excellent biography written by Joseph Mitchell in 2006 as part of the Historical Perspectives series in *Copeia*. We refer all readers to that work for learning about the details of Ernie's life, from catching a copperhead as a Cub Scout to his various professional activities and passions. Because Mitchell (2006) is so complete, we decided instead to fill in the lines between his many accomplishments with remembrances of Ernie from some of his colleagues and from his own stories of his collecting trips in Mexico. From 1991 to 1996, Ernie published nine essays (50 pages) of his collecting trips to Mexico, spanning 1951–1964. These were published in the newsletter of the Louisiana Gulf Coast Herpetological Society. They are a treasure. Think about the Ernie you knew as you enjoy the excerpts from his collecting trips in Mexico and a few of the memories from his colleagues.

"As I sit on my porch to write this segment of my Mexican adventures I am distracted watching the antics of a pair of Carolina Wrens, *Thryothorus ludovicianus*, which have a nest above my head with five young hatched 2 and 3 days ago. The parents keep coming and going to get food for the young. They flit around the shrubbery and my Ginko tree, *Ginkgo biloba*, getting ever closer before they enter the nest. While they are fulfilling their household duties 2 Green Anoles, *Anolis carolinensis*, are displaying their dewlaps in the Ginko Tree near me, and Boat-tailed Grackles, *Cassidix major*, are on the ground and in my American Elm, *Ulmus americanus*. An idyllic way to write." —*Liner, 1995*, Mexico 1962.

"When I heard all this [the imminent passing of Ernie] on Monday, I wanted to reach out to his other family—his herpetology friends. I knew how important the herpetology world was to him and all the people that he had met along the way. I honestly can say, I didn't really know how important that he was to all of you. I knew that he was pretty important (after all not many people get a reptile named after them), but I did not know how important he was. I had a suspicion that he was more important than I knew. This was proven true via all the emails I received that I passed on to my mom to tell Ernie." —*Derek Prosperie, great nephew, in reaction to the impromptu listserve that developed as news of Ernie's imminent passing spread.*

"In the morning I again ventured out on this lovely road to Linares. At 24 miles west of Linares near San Jose de Iturbide I spotted an AOR black-tailed rattlesnake, *Crotalus molossus nigrescens*. It was a beauty and I figured my luck had taken a turn for the better. However, shortly after this my luck really turned bad. Just after leaving Santa Rosa Canyon (and the uneven rock road bed) I started hearing funny noises from my car. I looked under it and found oil leaking out. I had put a hole in the crankcase. What lousy luck. The closest place for repairs was Linares about 20 miles east. I decided to ride it in. Six miles west of Linares I spotted a DOR *Masticophis taeniatus ruthveni* in very good condition, so I collected it. After all, specimens were hard to come by and I could not let a little trifle like a hole in the crankcase keep me from adding another specimen to the collection. Upon getting near to Linares I believe everybody in town heard me coming. The car was really making loud noises, but it was still rolling. The mechanic shook his head. I really began to worry. He repaired the crankcase. Then he had to do a ring job on the valves. Next he found parts in his junkyard to repair the drive shaft. He worked from mid-afternoon until close to midnight before it was almost good as new. I spent the rest of the night in the car in his shop yard. At least my mind was more at ease. When it comes to fixing anything mechanical, especially cars, the only thing I know is how to find someone else to do it." —*Liner 1991*, Mexico 1951.

FIG. 2. Chili cook-off at SSAR-HL Meeting, Veracruz, Mexico, August 1987. Sherman Minton gets a sample of Ernie's chili while David Hillis and Mike Ryan (among many others) wait their turn. Photo by Kraig Adler.

"Thank you for your call early this morning and for sending out this very warm and touching tribute to your Uncle Paran. He was truly a unique individual and we will not see his likes again. It was a privilege to have known him and to be his friend. I know he had hundreds of herpetological friends around the world who will mourn his passing, but at the same time we will reflect on all the joy and pleasure he brought into our lives. "Ernie Stories" abound in the herpetological world and will be passed by word of mouth for many years to come to the younger generations. I will miss my nearly monthly chats with him, just talking about what's going on in the herpetological world. Ernie never had any hidden agenda. He liked everybody and let them know it. This generosity of spirit was therefore returned to him by all of us. In many ways, he was our Uncle Paran, too, our godfather who was looking after all of us in his kindly, generous ways." —*Kraig Adler, in an email to Derek Prosperie*

"At 3 miles south of Cortulla and Dilley, DOR *Crotalus atrox* were collected. These were just placed on the floor of the passenger side of the car until a roadside park showed up where I could pickle them. While driving along I felt something crawl across my feet. I looked down to see a rattlesnake crawling across them. Needless to say I almost had a heart attack. I very [slowly] slowed the car down and by the time I was able to stop the snake had moved back over to the other side of the car. I got my rake, moved out of the car to the other side, pinned it and sacked it. Apparently the snake had just been stunned with injuries because it died in the sack. This could have been serious due to a bit of carelessness on my part. Needless to say, I never made this particular mistake again." —*Liner, 1991a*, Mexico 1951.

"I first met Ernie at JMIH 2005 in Tampa while he was signing copies of his book (*The Culinary Herpetologist*). Dave [Sever] introduced me. I didn't see him again until LUMCON [the Louisiana herpetology meeting] 2007. He was taking down names for registration. I was quite surprised that he called me by my first name when I reached the front of the line for registration. My own grandparents don't even recognize me, let alone know my name, yet Ernie remembered me from one meeting two years previous. He was amazingly sharp, and obviously that carried over to his herpetological work." —*Dustin Siegel, graduate student*

"Whenever I think of Ernie, I think of the herp meetings in Lawrence KS in the 70's…Ernie had the most amazing footlocker! Some others may remember it as well; he was definitely one of the best at meeting preparation among all of us. He will be missed. Still have his cook book, too." —*Bob Drewes*

"I first met Ernie about 25 years ago and have been lucky enough to visit him many times in Houma. I can safely say that Ernie was the kindest, most considerate person I have ever known. On several occasions I took vanloads of students from Pennsylvania down to Houma to visit Ernie and sample his hospitality and fine cooking. Somehow, despite there being no room for anything more in his home, Ernie always managed to find a place to fit us all in and wouldn't think of having us stay at a motel. On one trip I brought Wolfgang Boehme from Germany on his first and only trip to America. The visit to Ernie's place was a highlight and Wolfgang wrote about it in summary of his trip that he published after his return.

Fig. 3. Ernie Liner on a field trip during the 1998 JMIH in Seattle. The expression on his face pretty much sums up Ernie's outlook—life was pretty good. Armed with snake hook and camera, of course he is collecting plants to take back home! Photo by Robert Hansen.

Like many people, I received a King Cake from Ernie every Mardis Gras. However, most of the mail that arrived at my house from Ernie was not addressed to me. Once Ernie learned that my wife Monica's family was from Louisiana she regularly received care packages of food, including jambalaya and beignets, and once red boudin, which he brought to a herp meeting in a cooler for me to bring home. After visiting our house and seeing that Monica collected antique glass insulators, boxes of insulators started showing up periodically too. I don't know how many people were recipients of Ernie's generosity, but it must have been hundreds. Ernie loved herping and he loved cooking, but most of all he loved people. His passing marks not only the loss of a dear friend but the end of an era, as he was among the last of the great 'amateurs' who, in his spare time, made contributions to herpetology that rivaled those of any 'professional.'" —*Aaron M. Bauer*

"After collecting Crystal Cave we went to another cave which had a large population of vampire bats and some frogs. While collecting frogs from the roof, I was clinging on to the sides of the cave on sky hooks and whatever grips I could find. I must have been about eight to ten feet up when I reached out for a frog on a stalactite and it broke. Down I came. It seemed like an eternity before I hit bottom. I landed on the back of my head in a big pile of bat…guano. Fortunately I had on an old straw hat. I had bruises all over, hurt all over, and had a hole in my right shin. I was covered with old and new bat guano and vampire bats were flying all over. I stunk. In my field notes I commented that I would probably have a scar on my leg for the rest of my life. I do, but it also took six months to heal thoroughly." —*Liner, 1991b*, Mexico 1952.

"Just got in from the Rio Negro to hear the dismal news of the passing of Uncle Ernie, as he was known to us youngsters at the herp meetings, I never had the opportunity to be in the field with Ernie, but he relived his field experiences with Fred Cagle, Chaney, and others with such vivid detail and enthusiasm at the meetings that you went away thinking you had been there too. I met Ernie in 1972 at the SSAR meeting in Albuquerque, his stories of Mexico may have helped wet my interest to spend over 25 years collecting in Mexico as well. He will stay alive with me forever." —*Dick Vogt*

"I met Ernie in the herp range at the University of Southwestern Louisiana (now the University of Louisiana Lafayette) in 1964. As all the testimonials attest, Ernie never met a stranger and conversation was always easy. Ernie sent me his papers, and either accompanied me or gave explicit directions to all the local collecting sites on which he published, such as the almost mythical (to me) Bayou Tortue.

It has been adequately said that Ernie was nurturing. He was certainly an inspiration to this 18-year old budding herpetologist.

Fast forward to my last visit with Ernie. He had fallen in his driveway, hit his head, and landed in intensive care at East Jefferson Hospital near my home. True to form, he complained about the work he should be doing. The next time I entered his room, Ernie was propped up with a tablet and copies of Lemos-Espinal and Smith's *Anfibios y Reptiles del Estado de Coahuila, Mexico* and the same for Chihuahua on the bed. Ernie was writing reviews of these massive books, and his comments on the content of the texts ended with his regaling me with more stories of his exploits in his beloved Nuevo Leon, Mexico.

A few excited phone calls about news of fellow herpetologists later, the phone rang and I was told Ernie was gone. Although I didn't spend enough time with him during our 46-year friendship (there is never *enough* time with Ernie), the fact that he was nearby—and active—was comforting. Now there is a void." —*Robert Thomas*

"After negotiating and sightseeing through Monterrey, I stopped at Horsetail Falls, 25 miles south of Monterrey for collecting and sightseeing. Collecting was lousy: I only collected 1 *Rana pipiens* and saw 1 *Cnemidophorus gularis*. No way to collect the lizard because at the time I was riding a burro. For some reason I could not make the beast understand English, and besides, it had a mind of its own. I decided then that I was not meant to ride burros and never have since." —*Liner 1991a*, Mexico 1951.

"On this sad day, hello to all. I am greatly saddened to hear of Ernie's passing. I am sure that some of you know that I met Ernie while I was a grad student at LSU sometime back in the Pleistocene. It was Ernie who, in fact, introduced me to the world 'south of the border.' He invited me to go with him to his beloved Mexico. That trip took us from one end of the country to the other. Quite a few states in Mexico went on my 'life list' on that trip. There was even a paper that came out of it.

Ernie was one of those people in our field of herpetology that help to keep it grounded in what is important to all of us... our animals...that is, the whole animal in its habitat that we are privileged to see if we wish to join them where they live. This is what Ernie did for me on that first trip to Mexico all those many years ago (now amounting to about 45 of them) and I will be forever grateful to him for offering me that experience.

Ernie was a unique presence in herpetology who gathered friends far and wide in our field. With my sincere condolences to all those who knew, appreciated, and loved Ernie Liner. It will be a long while until we see the likes of him again, if ever." —*Larry D. Wilson*

"While we were admiring our catch a rabbit hunter came by carrying an old blunderbuss. He saw our .22 pistols and became interested. We were using rat shot and we showed him our shells. He had us shoot at an *Opuntia* (cactus) leaf to see our pattern. We did so and he was not too impressed. He then loaded his piece by placing powder, and packing it with some dried cow dung, placing some shot, and then more dung. He fired at the leaf and blew it all apart. Both of us commented that we would not want to eat the rabbits that he brought home." —*Liner 1996*, Mexico 1964.

"I met Ernie during my four years at what was then USL, in Lafayette. He was nearly always on the road for the drug company he worked for as his 'real job.' But he did stop by a couple of times. Usually I would see him at meetings though, like everyone else. As Dick Vogt noted, his enthusiasm for collecting was unmatched. Whenever we did have a chance to visit, the conversation was always about herping in Mexico, not about Louisiana. At one meeting I told him about collecting several populations of *Hyla* [=*Tlalocohyla*] *smithi* and *Hyla* [=*Tlalocohyla*] *picta*, on opposite sides of Mexico, and that I was analyzing the calls and would probably do a paper on them. The next week I received his entire collection of those species in the mail, for me to use in that study—he was also very generous. Since I left Louisiana for Arizona, we lost touch, but I will always cherish my memories of that man. He made meaningful contributions to herpetology, and brought joy to most anyone in his presence. I will certainly miss him, like the rest of you." —*Jack Fouquette*

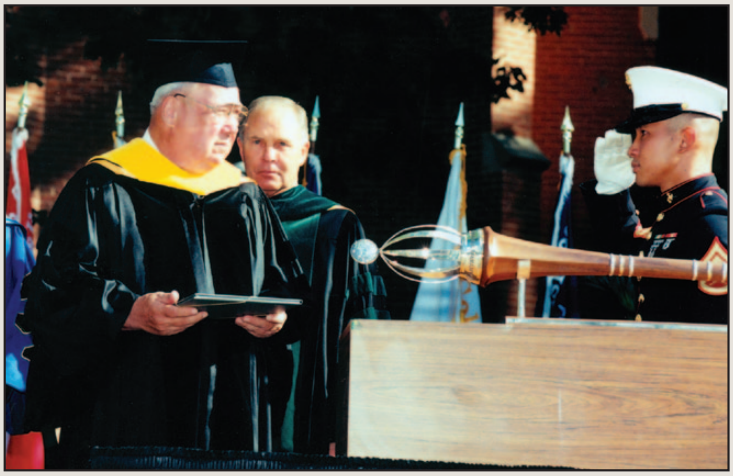

FIG. 4. Hooding ceremony, 8 August 1998. Ernie receives honorary Doctorate from the University of Colorado. Marine honor guard provided because of Ernie's WWII service in the Marines, Pacific Theater. Photo courtesy of University of Colorado.

"As is typical of collecting in Mexico (especially near villages) you soon pick up a retinue of followers, not always children. They were really excited when I just grabbed the coachwhips by hand and got bitten, as usual with them. I had an enjoyable day and pleasant dinner with the people of the village…as well as getting a nice assortment of herps from a remote area." —*Liner 1992a*, Mexico 1954.

"Some of my fondest memories of the joint meetings are the time I was able to spend with Ernie. Very often, I seemed to serendipitously come upon him at the airport on the way there (he usually looked like he was lost) and also have the opportunity to share a taxi ride on the return trip. I can't even put into words the pleasure those times brought me—and just when you were positive that he was the prototypical absentminded professor, he said something so astounding that it brought you back with a jolt. When we had differing opinions on details (and I was always wrong), he never argued, just smiled—reminiscent of the Grinch.

The incredible amount of knowledge I brought away from these encounters will always stay with me. I have always been amazed at his insightful approach, attention to detail, and sheer depth of knowledge, to say nothing of his dogged persistence and determination to complete seemingly insurmountable projects. He got that glow about him when he discussed his bibliographies and new projects. When he inscribed my copy of his first cookbook, I remember him telling me that there would be a second, even larger and better edition. It didn't seem like that would ever come to pass—who knew. But I'm very glad it did. I especially enjoyed our discussions about cooking and old dusty herp books.

He always had a ready smile, an amazing positive attitude, and never a harsh word for or about anyone. And I'm quite

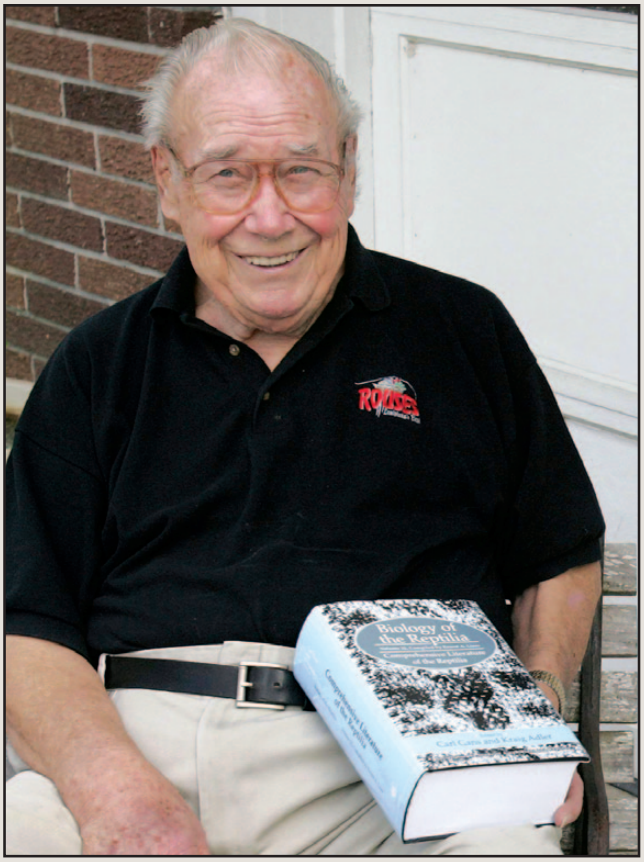

FIG. 5. Ernie with his big new book, *Comprehensive Literature of the Reptilia*, February 2010. Photo courtesy of *The Courier*, Houma, Louisiana.

sure that I never heard ill spoken of him. But that is just the kind of person he was. And you knew he was about to say something of great import when he preceded it with that Ernie grin. Both editions of his cookbooks sit at the entrance to my library separate from my other books and always will. Where else could you put them? They fit into no other classification or convenient niche—just like Ernie. I was honored to call him my friend and like so many others, will miss him immensely." —*Chuck Schaffer*

"At this location I received a great fright. While moving around trying to find more lizards I became aware of what I considered to be a mess of rattlers. They seemed to be all around me but I couldn't spot a single one. After awhile it dawned on me (I'm pretty dense sometimes) what was making the rattling sounds. It was locusts (grasshoppers) moving around in the dry vegetation and giving the impression of rattling sounds. For a while I was scared to move." —*Liner 1992b,* Mexico 1958

"I met Ernie shortly after arriving at LSU as a graduate student in 1966. A bunch of us were invited to one of Ernie's parties in Houma. The variety and amount of food was amazing, not to mention the iced beer. One of the memorable things in visiting Ernie was roaming his house looking at his books, journals, and various art works. However, the best was being in the company of an intelligent and always friendly person. Although I have not seen him often in recent years I will miss him." —*Ken L. Williams*

"I can hardly see through my tears to write this. I had read on a US Marine Corps web page something about the book *Flags of Our Fathers* written by James Brady and published in 2000. It covers in great detail the lives of the five Marines who raised the American flag on Iwo Jima in 1945. I had a copy on my shelf so I read the first part and then later, well into the night, got to reading to the end of the book. I don't usually do that but got caught up in reading a passage near the end and kept on going. Once I finished, I closed the book, feeling sadness over what happened to those boys and how it all affected their lives afterwards; those who were not killed on Iwo that is. I leafed through it and found a signature on the Library of Congress page – *Ernest A. Liner*. I could not believe it. I burst into tears and cried for a long time. Ernie was there. There in the book. There on Iwo Jima when the flag was raised. That immortal shot by Joe Rosenthal of the flag raising that captured American hearts and imagination, the photo that captured the essence of the US Marine Corps, that icon of the Marines. Ernie was there. He saw that flag fluttering in the South Pacific wind. Ernie died a few weeks ago. He did his duty on Iwo like everyone else. As a trained demolitions expert, he killed the enemy with satchel bombs by crawling to the top of concrete machine gun pill boxes and heaving the satchels inside through the small openings over the edge below. He was wounded there, but he came back alive and healed. He healed so well that, unlike most other men, he did not have nightmares about the ordeal and experience. I interviewed him about his life as a herpetologist for the Historical Perspectives section in *Copeia* and included a paragraph on his contributions as a combat Marine. I described his actions on Iwo Jima and how he was wounded. I felt great sadness upon learning of his death. But I never cried, at least until now. I clutched the book, ran my fingers gently over the signature and cried hard. Ernie was a Marine, a fellow Marine, a brother warrior Marine. How could I not cry over losing him, over the loss of yet another Iwo Jima Marine to time and history? Ernie was a hero in my book and a hero by any definition. He loved life, loved herpetology, loved Cajun cooking, and loved people. All of my colleagues who knew him respected and loved him for the kind of person he was, in part a herpetologist who made substantial contributions to that field. I loved him for being a fellow Marine. We shared a common bond, the bond forged by being a part of a brotherhood within a highly respected organization. We both paid the same dues to become part of that organization. We shared the common history of all the Marines that came before and those who will come after. We were connected in ways most will never understand. I miss Ernie. I want to talk to him more about his Marine Corps and war experiences. Unfortunately, that will never be. I can only cherish the memories I have of my brief times with him at meetings, of my interview with him for the article in *Copeia* that covered three days in his home in Houma, Louisiana, and of his thoughtfulness and kindness to others, myself included. I do not know where I got that copy of Brady's book. I still cannot remember getting it from Ernie, tho' I am sure I did. But there, on that page, was his signature. How did I come to get

this, I pondered? It haunted me as if it was somehow destined for me to find out this way, after reading the end of the book. And then I saw an odd piece of paper sticking out from inside the back cover. I turned to the back and found a white circular paper. Turning it over I saw the following words on the sticker: "RCA, Registered Coonass, 'Ain't Worried bout Nothin' " with a raccoon on the front. Well, it was Ernie's Cajun way of telling me to lighten up, to stop being mournful. Life goes on, as did his after Iwo Jima. He did his time. Now it is time for me to get on with what is left of mine. Thanks, Ernie. *Semper fi*. Always." —*Joseph C. Mitchell*

"At 0.6 mi. NW Guasave, I stopped at a pond alongside the highway which had a turtle swimming in it. I collected a few tadpoles, and saw an algae in it that I believed to be *Elodea*. Started in after the turtle with a dip net and a rake. I soon realized my mistake, as I began to sink rapidly in a quicksand-like substance. I anchored my tools into the solid ground and used them as leverage to pull myself out, losing my shoes in the effort. It was a frightening experience, but after replacing my shoes, I again headed north, though by then I lost all interest in the turtle!" —*Liner 1993*, Mexico 1960.

"I too share the warm feelings and sentiments expressed in all the emails I've seen. Ernie was a true prince. We first met in 1972 when Ray Ashton and I were on a toad collecting trip to supply Shelly Guttman with specimens for his systematics studies. Ernie had never met us before, but we were as warmly received into his home as if we were long time friends.

After a splendid meal of shrimp and crawfish boil, he offered to show us some local collecting areas. I offered my Dodge Power Wagon as transport—the go-[almost]anywhere vehicle of the trip. 'Naw... Let's take my company car.' So we piled into this plush Buick, me thinking we'd collect off some paved road. HAH! Ernie skillfully piloted that land-yacht out of town, OFF the road, and through sand, mud, and standing water that I'd have hesitated to drive the Dodge into! But Ernie of course knew the terrain and how deep the gunk was, so we just pushed on in to his spots and collected!

Well, afterward of course we were, ummmmm..., a MESS. But Ernie just said to pile in (we did set down some towels) and back through the goo we went to his house where there were more crawfish and shrimp to eat up, washed down as before with an appropriate libation.

Over the years since, we met at meetings and always spent time just yakking about all manner of things. And of course I have his cookbook! Not long ago, he mailed me a copy of a Houma magazine that had done a very nice profile article about him. I emailed him to thank him, assuming he got the email (Ernie never replied via email, but whenever I emailed asking for this-that info, it always arrived so I'm sure he read email).

Fond memories of a truly wonderful man. I'm having trouble typing through increasingly misty eyes, so I'll stop after saying to Derek and the other family that it's obvious Ernie touched so very MANY lives in diverse positive ways. Peace and good memories." —*George Pisani*

"Upon arriving near Galeana I saw Mexican vaqueros (cowboys) riding horses into the town. It seems they were going to a dance this Sunday night. I stopped at a local store in town near the plaza which had a lot of people milling around. I became an attraction and was told that cars could not make the trip—only busses and trucks. New ones became old very quickly. I was warned by the locals that since I was camping out I must be on the look out for banditos. They still had them around.

I made camp off of the road to the west of town for the night. Around eleven that night I suddenly had my camp surrounded by the vaqueros I saw earlier. They insisted that instead of my staying at my camp I must come to their rancho (which I now believe to be Rancho de la Montana). Upon arriving at the rancho one of the guys disappeared into a building emerging with a case of cerveza (beer). I was expected to pay for it, which I did. After we drank the beer we went to a tanque (pond) to look for sapos (toads) and ranas (frogs). We didn't find any so they went to bed and I slept in my car. The next morning they brought me fresh milk and cookies for breakfast. A little later in the morning they started chasing lizards for me on horseback. It was really hilarious watching them try to catch them. They did succeed in collecting 5 specimens of *Sceloporus parvus parvus*. After fooling around with them most of the day, and not collecting much, I decided to leave them to head back to Linares. After finding my way back to Galeana I again camped out just west of town, but this time I had no nocturnal visitors to interfere with my sleep."—*Liner, 1991a*, Mexico 1951

"As one ages one of the saddest things is the increasing loss of friends. No loss to me has been sadder than that of Ernie Liner.

I first met Ernie in the 1960s when he led a field trip at a herp meeting in New Orleans. He took us to an incredible spot where the bus load got a huge number of herps, mostly some fine snakes. One of my students needed copperheads, under one sheet of roofing tin we got four.

My greatest respect for Ernie was his empathy and kindness shown me and my family over the years, having little to do with herpetology. When one of my sons died, I was in deep depression. Ernie invited me to come visit him. With a geologist friend we drove through a severe ice storm to Houma, where Ernie's kindness was a big help. It was on this visit that he took us through the Mississippi delta—Chauvin, Boudreaux, Dulac, Cocodrie, etc. Of course, he fed us well!

When my granddaughter was five and after her father died, we had to go through a lot to get her out of a dangerous environment and become her legal guardians. When Ernie heard of this, here came an 'Ernie care package' full of very appropriate items for a five year old. He later sent her dozens of Mardi Gras beads and trinkets, which she still cherishes. Similarly, several times Ernie sent my wife care packages with spices and food items available only in Louisiana.

Several trips with Ernie were also memorable. In the 1980s he drove to the herp meetings in San Francisco, collecting along the way, including some rattlers. He drove us and Meg Stewart and her spouse to Point Reyes and surrounding areas, along with the menagerie he had assembled in his Dodge Ram. He and I drove from Norman to a SWAN meeting in Kansas, birding along the way at the Great Salt Plains, Cheyenne Bottoms,

and other refuges where we saw huge flocks of migrating sand hill cranes, white pelicans, and numerous shore birds.

Ernie shared his many joys with me (as he apparently did with his many other friends), especially his honorary doctorate from Colorado. After he was selected to receive the research award from SWAN a few years ago, I had the privilege of calling him to give him the news. I could hear the tears of joy and humility in his voice. He was truly a humble man." —*Vic Hutchison*

"I pulled into El Naranja into a small hotel along the Rio El Salto. I was one beat gringo not having been to sleep in two days but before retiring collected 8 Gulf Coast toads, *Bufo valliceps*, and 2 common Mexican treefrogs on the highway and along side it at the river.

With the roar of the river singing a lullaby I had a good, sound sleep. Upon arising in the morning and while I was in the bathroom I found my first herp of the day. Under the lip of the toilet bowl a veined treefrog, *Phrynohyas venulosa* [=*Trachycephalus venulosus*], was collected." —*Liner 1994*, Mexico 1961

"I knew Ernie a bit from the SSAR meetings, but after I moved to Louisiana in 1991, I had the pleasure of really getting to know him. We spent time on the phone and at the biannual Louisiana herpetology meeting down in Cocodrie, talking about this and that in herpetology, but that's not how I really got to know him. Ernie had a habit of just getting into his car and visiting unannounced. It was always a great pleasure to see him so I would drop everything and do work if we needed but invariably we would go eat, usually with herp grad students in tow, and all the while talking about herpetology. As he got more involved in the second edition of his Standard Spanish and English names list of Mexican reptiles and amphibians, we spent more and more time talking about names. We did not always agree, but that was fine with both of us and the differences are evident in his publication (Liner and Casas-Andreu 2008). The amazing thing about these visits, was that sometimes I would be in class or in a meeting so Ernie would just find a bench near my office and sit. He always had something to read, but I know that sometimes he sat for over an hour! I always felt bad about him waiting around, but Ernie would have none of that and give his broad smile accompanied by an offhand comment saying he was perfectly content. I finally got to give all those visits back to Ernie. Just before he passed I (along with Cliff Fontenot) raced down to Houma to see him in the hospital. He could not speak much, but at the end of the visit I said I would see him at Cocodrie in November and very audibly he said, 'I hope so.' Ernie, thanks for everything."—*Brian Crother*

"This ad hoc list-serve has brought to attention stories of kindness and generosity stemming from Ernie that are beyond comparison. I knew he was a nice guy, but I was unaware of the depth of his devotion to giving and support.....truly humbling to read of this great person. I will say that I never knew Ernie particularly closely, so these stories we've been relating are especially eye-opening. I met him first soon upon arriving at my first-ever annual Herp Meeting (hosted by Tulane, in 1990 I believe). I was a first-year Master's student, I was nervous, and I was awed to see names I knew from the literature and specimen tags on name tags! Ernie spotted me early in the conference, introduced himself, and made me feel extraordinarily welcome and at ease through the entire week; he checked up on me at least once every day. Ever since, at every conference, he would always make a point of asking me something friendly and implicitly supportive like "Hi Joe, are you still chasing those *valliceps* toads?" That meant a lot to me, to simply be recognized and remembered from year to year at the meetings."—*Joseph Mendelson*

"I can simply say that my coonass friend Ernie, like only a chosen few, was one of those special guys who should be allowed to live forever." —*Charlie Painter*

"As all good things must come to an end, I then had to go home…." —*Liner 1993*, Mexico 1960

Acknowledgments.—We are extremely grateful to everyone who allowed us to use their personal comments about Ernie: K. Adler, A. Bauer, B. Drewes, J. Fouquette, V. Hutchison, C. Painter, G. Pisani, D. Prosperie, C. Schaffer, D. Siegel, D. Vogt, K. Williams, and L. Wilson. Bob Hansen kindly sent a digitized copy of Ernie's *Mexico Bound* essays. Kraig Adler generously shared a number of articles about Ernie as well as the photos. Mary White is thanked for reading and editing drafts.

"The Chinese have an idea that the Alligator is wonderfully tenacious of life. The Canton annals say that the head can be cut and dried, before the animal dies, the muzzle can be broken into pieces and all the teeth pulled out and it still lives."

—Albert-Auguste Fauvel, *Alligators in China: Their History, Description and Identification*, 1879:12

Chinese Alligators (*Alligator sinensis*) have been an integral part of zoo collections for many decades because they are hardy in captivity and not subjected to the assaults described above by Fauvel. One lived at the Bronx Zoo (Wildlife Conservation Society) in New York for over 46 years (Snider and Bowler1992). In an early account, Lederer (1941) described care of the Chinese alligator at the Frankfurt Zoo. There is an interesting photograph of a London Zoo keeper holding a tame alligator in the book Marvels of Animal Life by W. S. Berridge in 1926. Müller (1970) mentioned reproduction at the Leipzig Zoo. Behler (1977) described the excellent propagation program for Chinese alligators which involved a number of zoos and the Rockefeller Wildlife Refuge in Grand Chenier, Louisiana where the alligators were maintained in a semi-captive environment. For example, a pair was acquired by the Smithsonian National Zoological Park in 1937 and the female never reproduced for forty-three years until transferred to the Refuge when 8 young hatched there from 21 eggs. Behler et al. (1982) and Brazaitis and Joanen (1984) documented the status of the species and propagation in captivity. Davenport (1982) discussed reproduction and aging and Watanabe (1986) felt hopeful about its future.

In 1879, Albert-Auguste Fauvel published the first scientific description of the Chinese Alligator (Alligator sinensis) in Alligators in China: Their History, Description and Identification. Shown here are plates from his original monograph. It is a pre-print of an article published in the 1879 volume of the Journal of the North-China Branch of the Royal Asiatic Society. Credit: courtesy of Tim Perry and Kraig Adler.

Although there are thousands in captive breeding facilities, fewer than 300 individuals exist in the wild. This taxon is considered to be the most endangered crocodilian in the world. The late John Thorbjarnarson from the Wildlife Conservation Society in New York and Xiaoming Wang from East China Normal University have published a book with up-to-date information on this imperiled crocodilian (2010, The Chinese Alligator: Ecology, Behavior, Conservation, and Culture, Johns Hopkins University Press, Baltimore, Maryland; ISBN-13:978-0-8018-9348-3; 10:0-8018-9348-8; 265 pp.). In their book, the authors cover many topics: crocodilians of the world, ecology and behavior, habitat and population status, and its future.

There are captive management plans in place by the Association of Zoos and Aquariums (AZA) in the United States, The World Association of Zoos and Aquariums (WAZA), and the European Association of Zoos and Aquariums (EAZA) which include population analysis, studbooks and recommendations on breeding and transfers to prevent inbreeding depression.

Snakes in Trees

For twenty years, Richard A. Sajdak was Curator of Herpetology at the Milwaukee County Zoo in Wisconsin until retirement. He has a fascination with arboreal snakes and has written an interesting book about them. In fact, virtually everything yo-would ever want to know about tree-dwelling serpents is contained in this book. The title is *Hunters in the Trees. A Natural History of Arboreal Snakes* (2010, Krieger Publishing Company, Malabar, Florida, ISBN-13:978-1-57524-303-0; 10:1-57524-303-2). Sajdak coordinated an admirable research program at the Zoo, publishing over 40 articles and book chapters. Selected Sajdak publications and descriptions of the Zoo's herpetological history are listed below:

Historical Overview

Card, W., and J. B. Murphy. 2000. Lineages and histories of zoo herpetologists in the United States. Herpetol. Circ. 27:1–45. [portrait of Richard Sajdak]

Speidel, G. 1969. Aquarium and reptile building at Milwaukee Zoo. Inter. Zoo Yearb. 9:71–72.

Zucconi, D. 1967. Impressive new aquarium and reptile building for Milwaukee County Zoological Park. Herpetol. Rev. 1(1):9.

Zucconi, D. G. 1968. Reptile & amphibian exhibits in the Milwaukee Zoo's new Reptile/ Aquarium Building. Bull. Philadelphia Herpetol. Soc. 16:21–30. [Contribution was the last on reptile buildings in the United States. Photographs of the building, public areas, rear section, a very young David Zucconi, who was Sajdak's curatorial predecessor and a few alligators were included.]

Conservation

Sajdak, R. A. 2001. Patriarchs of the bluffs. Fauna May/June:8–21. [description of long-term monitoring study on Timber Rattlesnakes in Wisconsin]

There are beautiful plates in Alfred E. Brehm's *Les Merveilles de la Nature. Les Reptiles et les Batraciens* (Librairie J.-B. Baillière et Fils, Paris, 1883). Brehm was Director of the Hamburg Zoo in Germany from 1863 onward and founder of the Aquarium Unter den Linden (Berlin's main street) in 1869. This Long-Nosed Tree Snake (*Ahaetulla nasuta*) is found throughout India, Sri Lanka, Burma, Thailand, Cambodia, and Vietnam.

Important Article for Zoo Ecologists

Sillero, N., and P. Tarroso. 2010. Free GIS for herpetologists: free data sources on Internet and comparison analysis of proprietary and free/open source software. Acta Herpetologica 5(1): 63–85.

Box(ed) Turtles

Dave Fogel provided this cardboard shipping box used to send baby painted Red-Eared Sliders through the mail. It was used ca. the late 1950s or early 1960s. Imagine the trauma, dehydration and temperature variation encountered by these entombed chelonians.

Cardboard shipping box used to send baby turtles through the mail. "Neither snow, nor rain, nor heat, nor gloom of night stays these couriers from the swift completion of their appointed rounds "— unofficial motto of United States Postal Service.

Hopelessness

In recent years we have noticed a worrisome trend among our colleagues in conservation biology: a continuing culture of despair. This culture manifests particularly in conference presentations, most recently at the 2009 annual conference of the Society for Conservation Biology in Beijing. Many young, emerging conservation biologists could be heard questioning, "Where's the hope?" and expressing despair at the gloominess of many presentations and discussions.

"The Culture of Conservation Biologists: Show Me the Hope!" by Ronald R. Swaisgood and James K. Sheppard
—*BioScience* September 2010 / Vol. 60 No. 8:626–630.

Ronald R. Swaisgood <*rswaisgood@sandiegozoo.org*> is the director of the Applied Animal Ecology Division, and James K. Sheppard <*jsheppard@sandiegozoo.org*> is a postdoctoral fellow at the San Diego Zoo's Institute for Conservation Research.

Shifting Baselines for Herpetologists

Virtually all of the papers I read about amphibian decline are impersonal and this is appropriate because these are technical papers. Joe Mendelson's essay that follows is unique because it tells the reader what it FEELS like to watch the loss of amphibians and how this event changed his life. I sent this essay out for review and got back some interesting reminiscences and thoughts; I will share some of them in my next column.

Shifted Baselines, Forensic Taxonomy, and Rabbs' Fringe-limbed Treefrog: The Changing Role of Biologists in an Era of Amphibian Declines and Extinctions

My initial foray in tropical herpetology yielded less than spectacular results. In 1989, I was a new graduate student at the University of Texas at Arlington, where my mentors, J. A. Campbell and E. D. Brodie Jr., arranged for me to spend a field season in Guatemala. My task was to make collections on the wet northern slope of the Sierra de las Minas, based out of Finca Pueblo Viejo, a coffee/cardamom/rubber plantation at the edge of the Polochic Valley in Alta Verapaz (Mendelson 1990). This region of the sierra had never been surveyed herpetologically, so I was very excited to conduct an expedition.

As this was to be my first experience in the tropics, I "did my homework" in terms of relevant literature, available field notes, and especially reviewing the collections at UT Arlington. Consequently, when I arrived at the site and despite my inexperience, I was fairly knowledgeable of the animals I might encounter. I knew to look on the underside of leaves for centrolenid frogs, and to dig in piles of rotting coffee-bean husks for caecilians. I knew to look for species of frogs in the *Craugastor rugulosus* group on the ground and rocks along montane streams. That summer, I assembled a good collection of reptiles from Pueblo Viejo, but a poor collection of amphibians.

Late summer and fall, I sorted and identified my specimens. I was pleased to realize that I had, for the first time in my career, discovered a species new to science: *Incilius campbelli* (Mendelson 1994), a toad previously confused with the ubiquitous *Incilius valliceps*. One day, while I had some frogs out in a tray, Jon Campbell pointed to a specimen of the *Craugastor rugulosus* group (later described as *C. sabrinus* by Campbell and Savage 2000) and asked why I had collected only one of those. I responded "*Because that's the only one I found*." It seemed clear to all concerned that Mendelson's inexperience explained the paucity in the collection of these typically common streamside frogs. Meanwhile, down the hall in his lab, Campbell was frustrated in his attempts to describe the tadpole of a new species of *Ptychohyla* from Guatemala (Campbell and Smith 1992) because—for some reason—none of the specimens collected by Eric Smith (then an undergraduate in Guatemala) had complete mouthparts.

That same month, September, hallway conversations at the First World Congress of Herpetology, held in Canterbury, UK, were considering that amphibians might possibly be in decline (Wake 1991). It would be several years yet until Joyce Longcore and colleagues described the insidious chytrid fungus that destroys the mouthparts of tadpoles as it proceeds to decimate amphibian populations (Longcore et al. 1999). But it would be a long time before I realized that the paucity of specimens of *C. sabrinus* in my collection was not the result of my tropical inexperience.

In 1992, my friend Adrian Nieto-Montes de Oca and I spent the summer in southern Mexico, looking for anoles and toads for our dissertations at the University of Kansas. I took along photocopies of field notes by Bill Duellman, Jan Caldwell, John Lynch, and others made in the 1960s and 1970s to help guide our efforts at certain sites. That trip was frustrating because, despite our best attempts, Adrian and I could not come close to duplicating the successes of the earlier collectors. For example, field notes indicated that salamanders of the genus *Thorius* could easily be found by the dozens or even hundreds in Oaxaca. We found one *Thorius* that summer, and it was a new species (*T. smithi* Hanken and Wake, 1994).

Around this time I became friends with Karen Lips, a graduate student from a "competing lab" (Jay Savage's group at the University of Miami), who had interests similar to mine but with field sites that were further south, mostly in Costa Rica. She and I often discussed our experiences and compared notes from our respective field adventures. She told me of working cloudforest streams at night and finding dozens and dozens of frogs, whereas I was hard-pressed to find dozens of upland frogs in Mexico during an entire season, much less a single night. We didn't think much of the disparity at the time, but I will be honest in admitting that I was worried that my life-long southern California field skills were not serving me well in the tropics. In the mid-90s I travelled extensively with Jonathan Campbell and Eric Smith, mostly in Guatemala, and it became obvious that they too could not find appreciable numbers of amphibians including the "common" species of the *Craugastor rugulosus* group or upland hylid frogs. I clearly remember a day in 1996, when I stood with Campbell at the type locality for *Plectrohyla cyanomma* (Caldwell, 1974) in the Sierra de Juárez, Oaxaca, and he pointed to a particular rock in the stream and commented that he inevitably found individuals basking on that rock, and the stream was always replete with their large tadpoles. There were none.

During those times in the late 80s and the 90s, it never occurred to me that I found few amphibians on my trips because they simply were no longer there. It is clear now that I began my career in tropical herpetology in a geographic arena (Mexico

and Guatemala) that had experienced a dramatic baseline shift in amphibian diversity and abundance before I ever arrived. As we were to discover, Karen Lips began her career in a geographic arena (Costa Rica and Panama) that was just on the verge of having its baseline shifted. When it did so, I am glad at least that she and her collaborators were able to describe that shift in great detail. They were there to document one of the great stories unfolding in natural history during our times (e.g., Lips 1999; Lips et al. 2006; see also Collins and Crump 2009). As for me, I got but a single glimpse at an intact Mesoamerican amphibian community in central Panama in 2005, just months before it crashed. All told, I personally feel like I was cheated of a natural history experience that I deserved and I am angry about it. I also am sad that current and future cohorts of graduate students and naturalists will share this loss. There no longer exists a natural upland ecosystem in Mesoamerica.

Nobody noticed the declines taking place in Mexico and Guatemala. In 2000 Karen Lips and I led resurveys of historical collecting sites in southern Mexico that had not been visited in years, and concluded that a subset of the amphibian fauna was simply missing and what species did remain in the higher elevations were far less abundant than they had been historically (Lips et al. 2004). Our reasonable estimate was that the declines there took place in the mid-1980s. That summer we found exactly one individual representing the entire *Craugastor rugulosus* group. Similarly, in Guatemala, the remnant amphibian fauna of a cloudforest reserve, Biotopo Mario Dary in the Sierra de las Minas, Baja Verapaz, bears little resemblance to its historical assemblage and abundance, based on Campbell's field work there ca. 1980 (Mendelson et al. 2005). If you wish to know the details of how a decline like these comes about, then do read the important paper by Ryan et al. (2008) wherein they describe the final days of a population of *Craugastor* cf. *punctariolus*. We now believe that species to be extinct in the wild (Griffiths, Ross, and Mendelson, unpublished data), but taxonomists are not entirely sure as to what species it was.

It is reasonable to conclude that the chytrid fungal pathogen *Batrachochytrium dendrobatidis* Longcore, Pessier, and Nichols, 1999, played a major role in eliminating amphibian species and reducing their populations in Mexico and Guatemala (Lips et al. 2004; Mendelson et al. 2005) in the 1980s, but of course this is difficult to demonstrate directly in retrospect. Although histological examination of museum specimens (where sufficient series of specimens exist, which is unusual) might identify synchronous appearance of the fungus and subsequent population declines, correlation is not causation. Quite frankly, such studies are psychologically depressing, and I have noticed that few students delve into them. It is not very rewarding to study a population or species so recently vanished.

Herpetologists spent the better part of the 1990s aggressively debating the reality of amphibian declines and potential causes (reviewed by Collins and Crump 2009) and, meanwhile, the situation became worse. The baseline shift that I missed means that, despite my 20 years of field work and research in northern Mesoamerica, I have never experienced a natural amphibian community there. The baseline shift that Karen Lips and colleagues are documenting in southern Mesoamerica means that no herpetologist visiting the area in the future can ever possibly know the historical reality of those ecosystems.

When an epidemic of chytridiomycosis decimates a regional amphibian assemblage, the ecosystem there is fundamentally changed (Lips et al. 2006; Smith et al. 2009; Crawford et al. 2010) and those changes have ecosystem-level effects (Whiles et al. 2006; Connelly et al. 2008). A national park near El Copé, Panama, lost at least 30 species of amphibians (41% of the assemblage; Crawford et al. 2010). The fully-protected Biotopo Mario Dary in Guatemala appears to have lost about 70% of its amphibian fauna (J. A. Campbell, pers. comm.). When you consider losses of this magnitude together with the phenomenal biomass that amphibians may attain (Burton and Likens 1975), it is impossible to assume that the affected ecosystem will function in any manner similar to pre-epidemic conditions. The implications of these faunal upheavals are considerable, and they are generally ignored outside the research community that is directly related to amphibian declines. Biologists of all sorts should acknowledge if their research is taking place in the context of an intact, or an altered, amphibian community. Would not a cardiologist also consider the fact that their patient has emphysema? The reality of amphibian declines and extinctions has shifted the ecological baseline in so many ecosystems, that an entire generation of biologists is conducting their research in a framework that has been very recently remodeled. And I feel like we—herpetologists, ecologists, biogeographers,

systematists, and more—are not really talking about it; this reality compromises our research, and this is a problem.

I am a taxonomist and I have seen my career vacillate between the thrill of discovering new species and the chill of tracking extinction events—including species that I described. Taxonomists are not the warmest lot of people, but I will opine that one feels a personal connection with a species that you yourself have named. In a recent species description (Mendelson and Mulcahy 2010) we put forward the term "Forensic Taxonomy" to try to communicate the frustrating reality of what it means to be an amphibian taxonomist in this era. In the last 20 years, I have contributed to naming (or resurrecting) 32 amphibian species. Of these, I believe at least four of them are extinct, and several others are hanging on in very low numbers. I have never seen several of them in life, having described them based on specimens on the shelves of museums. I sought a career in herpetology because I enjoy working with animals. I did not anticipate that it would come to resemble paleontology. I am not alone in this cutting-edge new field of Forensic Taxonomy, as I note that my friend Luis Coloma (Coloma et al. 2007, and especially Coloma et al. 2010) has independently discovered the field as he works his way taxonomically through the ashes of what once was the wonderful radiation of *Atelopus* (LaMarca et al. 2005). I focus most of my attentions on frogs, but the salamanders are in no better shape (Parra-Olea et al. 1999; Rovito et al. 2009), and the poor caecilians perpetually languish in the cloud of our ignorance of their fascinating habits.

The US National Science Foundation has an entire program devoted to Biotic Surveys, and I endorse that program entirely. However, I must pose the question "*What does it mean to conduct biotic surveys in an era of shifted, shifting, or soon-to-be shifted baselines of amphibian diversity*?" Crawford et al. (2010) discovered that even seven years of systematic collections of tissues, specimens, and ecological notes failed to discover a good proportion of the actual amphibian species-level diversity that existed near El Copé, Panama, prior to the epidemic of chytridiomycosis documented by Lips et al. (2006). Our discovery and description of *Incilius karenlipsae* Mendelson and Mulcahy, 2010, based on a single specimen found at that site in the wake of the disease, was an experience I can classify only as bittersweet because the effects of chytridiomycosis there suggest that it likely no longer exists. I hope I am wrong about that.

I can tell you what it feels like to conduct biotic surveys for amphibians in this era. In 2004, I joined Martín Bustamante to survey a site in southern Ecuador. That general region of the Amazonian slope of the Andes had never been surveyed herpetologically, so the project qualified as an expedition into an area undocumented by herpetologists—the kind of excursion that made H. M. Smith, E. H. Taylor, L. C. Stuart, and our other heroes legendary. We were on site for about a month, with a team of eager students, in what we thought was a pristine ecosystem along a cloudforest–paramo transition zone. In that month we found only seven species of amphibians—five *Pristimantis* spp., one *Gastrotheca* sp., and one dendrobatid; at least three of the *Pristimanis* spp. are new to science. Biannual surveys of the site in the last six years have not increased the numbers. Bustamante and I are working on describing these new species (e.g., Bustamante and Mendelson 2008), but it is apparent that our attempt to conduct a modern biotic survey came too late. Where were the hylids, the centrolenids, the bufonids, or the *Telmatobius*? What we surveyed was in no way a typical Andean amphibian fauna (see Duellman 1979), which should have harbored many more species. Local ranchers told us that the site used to include *jambatos* (= *Atelopus* spp.). They also provided perfect descriptions of a local *Telmatobius* sp. but they had not seen either frog in many years. The *Telmatobius* sp. likely was *T. cirrhacelis* Trueb, 1979, a species described as "possibly extinct" on the IUCN Red List (www.iucnredlist.org). We cannot hazard a guess as to the identity of the *Atelopus* spp. that had once existed at the site. Bustamante and I had gone into the area too late even to conduct a proper Forensic Taxonomy of the life that once existed there.

In late 2004, Karen Lips determined that the chytrid pathogen had finally arrived at her long-term study site near El Copé, Panama, and the expected massive die-off was in progress. This reality created a terrifying reality of predictiveness—we knew where it was going next, but we had no idea of what to do about it. In response to this important finding, an emergency meeting in Atlanta brought together a small group of key stakeholders to try to determine what, if anything, could be done about the situation there, as all precedents indicated that the amphibian fauna of the adjacent highlands of Panama were about to be

FIG. 2. JRM in Sierra de Huautla, Oaxca, Mexico, July 1992. No individuals of *Craugastor* nor *Plectrohyla* were found along this cloudforest stream. Photo by A. Nieto-Montes de Oca.

decimated by the disease (Collins and Crump 2009, provided more details about this meeting). Among the projects that resulted from that meeting was a pilot-study for the development of a rapid-response multi-species "extraction" of amphibians into captive safekeeping. This was to be launched near El Valle de Antón, just east of Lips' site at El Copé. This pilot project took place in 2005, and was described by Gagliardo et al. (2008).

Among the frogs collected at the El Valle site for safekeeping was a large fringe-limbed treefrog of the genus *Ecnomiohyla*. We assumed it to be *E. fimbrimembra* (Taylor, 1948), but our colleague Brian Kubicki (Costa Rican Amphibian Research Center) immediately recognized it as a new species. Eventually, we collaborated and described the species *Ecnomiohyla rabborum* Mendelson, Savage, Griffith, Ross, Kubicki, and Gagliardo, 2008. The name honors George and Mary Rabb, as lifelong stalwarts for conservation—especially for amphibians. It meant a lot to us to honor them with this spectacular new species. Edgardo Griffith and Heidi Ross (El Valle Amphibian Conservation Center [EVACC]) led the field work that discovered the frog and were able to document some of its amazing natural history (detailed in Mendelson et al. 2008). As is known in other species of *Ecnomiohyla*, the frog does leap from upper tree limbs and glide to the forest floor, using its massive fully webbed hands and feet to orient, and the eggs are deposited in tree holes. Edgardo and Heidi observed that the males remain with the developing eggs and immerse their body into the writhing mass of tadpoles on occasion, allowing the tadpoles to rasp their epidermis for nutrition. We believe this is the first example of direct paternal nutrition of offspring in an amphibian, but it appears that we will not have the opportunity to directly demonstrate such. In any case, this is an impressively large treefrog (up to 100 mm SVL) with a remarkable natural history. *Ecnomiohyla rabborum* was discovered afield in 2005 and formally named in 2008. In 2006, the chytrid fungus arrived at El Valle, having moved eastward from El Copé, in an advancing wave, exactly as predicted by Lips et al. (2006) and further characterized by Lips et al. (2008). Just as predictable was the utter decimation of the amphibian fauna there during 2006–2007, and our lack of any means of preventing it.

In 2006, crews at the nascent protection facility, EVACC (still under construction at the time!), scrambled to triage and treat infected frogs of many species, hoping to use them to establish captive survival-assurance colonies. Individuals of *E. rabborum* were distributed, for safekeeping, to facilities at EVACC, Zoo Atlanta, and Atlanta Botanical Garden. Captive programs for endangered species sometimes are successful (e.g., *Atelopus zeteki*, www.ranadorada.org) and sometimes they are not (e.g., Passenger Pigeon, as a singularly famous example). The end-story is that these individuals of Rabbs' Fringe-limbed Treefrog thrived for years but never bred under captive conditions. The last wild individual noted was a calling male heard (but not seen) in 2007. Edgardo and Heidi still lead field work in the area, but the species has not been found. The last female known died in captivity at Atlanta Botanical Garden in 2009. At this time of writing, a single adult male lives at the Atlanta Botanical Garden and another is at Zoo Atlanta (see cover image). It appears that nature has run its course before three teams of dedicated people were able to determine the needs of these frogs in order for them to reproduce. To have been a part of one of those teams has been a frustrating and sad experience.

Our esteemed colleague Tim Halliday—a longtime leader in the field of amphibian declines—has taken to calling himself "an extinction biologist." His sense is accurate, if morbid, and I posit that most of us working on amphibians in this era may consider adopting the term. As for me, I'm still adjusting to my new title of "Forensic Taxonomist." I have re-surveyed field sites and experienced the emptiness of not finding as many frogs as Bill Duellman did in the 1960s. I have co-led biotic surveys to places that are too ravaged to consider. I have named species from museum jars, lamenting all the while that I would never see them alive. But none of those feelings resonate like coming to my zoo everyday and seeing what is essentially the end of a spectacular species like Rabbs' Fringe-limbed Treefrog. There is no female that we know of, and one morning I will find the male at Zoo Atlanta dead of natural causes. I will collect tissue samples for phylogenetic studies, I will collect cells for San Diego Zoo's Frozen Zoo initiative (perhaps one day it can be cloned?), and then I will preserve the specimen for the museum shelf. Shall I post a video clip on YouTube so people can watch the frog move about, like the famous film clip of the last thylacine? Then I will return to my lab, take a jar off the shelf and proceed to describe another new species of frog that used to exist somewhere in the world. I am, after all, a Forensic Taxonomist.

It turns out that extinction is a difficult thing to demonstrate unequivocally, as it is founded largely on negative evidence. In my career, I never suspected that I would end up hoping to be wrong in so many of my academic endeavors. I am glad that we all were wrong about the extinction of Holdridge's Toad (*Incilius holdridgei* Taylor, 1952) in Costa Rica (Abarca et al. 2010). I hope we are wrong about the iconic Golden Toad (*Incilius periglenes* Savage, 1967) and that really it is simply underground (Crump et al. 1992), waiting out this entire ordeal.

Acknowledgments.—Field work over the years has been funded by a Theodore Roosevelt Memorial Grant from the American Museum of Natural History, the National Geographic Society, University of Kansas Natural History Museum Panorama Society Fund, a Tinker Field Research Grant from University of Kansas Center for Latin American Studies, and especially by grants to Jonathan A. Campbell (NSF: DEB-9705277, DEB-0102383, DEB-0163802). I am grateful to Jim Murphy for encouraging me to write this essay, to Mike Lannoo for similar conversations. Early rambling drafts of the manuscript were improved by helpful comments and insights from J. Campbell, H. Greene, K. Lips, S. Sweet, R. Altig, R. Brown, R. Gagliardo, D. Wake, P. Nanjappa, K. Adler, B. Lock, R. McDiarmid, J. Savage, J. Hanken, and J. Gallant. I am enormously grateful to then-Associate Professor J. A. Campbell for teaching my Intro Bio lab sections in the summer of 1989, so I could travel to Guatemala.

One Day to Hatch: Calcium-poor Eggshells and Maternal Care in *Ovophis okinavensis* (Squamata: Viperidae)

Reptile reproductive modes are defined on the basis of whether the females lay eggs (oviparity) or produce live young (viviparity) (Vitt and Caldwell 2009). Oviparous species have incubation periods ranging from more than six months to a few days (Köhler 2005). It is known that a Japanese pitviper *Ovophis okinavensis* lays eggs that hatch in an extremely short period (1–5 days, Koba 1959; Fukada 1964; Koba et al. 1970: 1–10 days (estimated), Nishimura and Kamura 2000) compared to other species of snakes (Köhler 2005). Eggs of *O. okinavensis* are characterized by partially transparent, thin eggshells through which the embryos are visible (Fukada 1964; Koba et al 1970). Nonetheless, no detailed structural examination of the eggshells has been conducted. In this study, we quantify the area of calcium covering the eggshell surface and the amount of calcium contained in an eggshell. In addition, because an evolutionary association between short incubation period and the occurrence of parental egg-guarding has been suggested (Tinkle and Gibbons 1977; Shine 1988), we present the first evidence of maternal attendance of eggs and neonates by *O. okinavensis* based on a field observation and a laboratory experiment.

Methods.—We collected six gravid female *O. okinavensis* in 2007 from three islands (Okinawajima, N = 3; Yanahajima, N = 2; Amamioshima, N = 1) in the Ryukyu Archipelago, Japan. The snakes were individually housed in plastic cages until oviposition.

The area of the eggshell surface covered by deposited calcium was measured for 6 eggs (clutches A (3 eggs) and B (1 egg) from Yanahajima and clutch C (2 eggs) from Okinawajima). We cut each eggshell and spread it out on a board to take a photograph of its surface. The photographs were imported into Adobe Photoshop CS 8.0, and calcium deposited and non-deposited areas were painted to white and black, respectively, by eye. The painted photographs were then captured to NIH Image 1.63 (available online from the US National Institutes of Health; http://www.nih.gov/), and the percentage of white area was calculated. The amount of calcium contained in each eggshell was measured using 4 eggs (a clutch from Amamioshima). For comparison, the amount of calcium was also measured for 3, 3, and 2 eggs of *Elaphe quadrivirgata*, *Rhabdophis tigrinus*, and *Protobothrops flavoviridis*, respectively. These eggshells were dried at 105°C for 1 h and then weighed. The dried samples were dissolved in NHO_3, and dilutions were made using 5% lanthanum chloride solution and distilled water. Calcium determinations were performed using an atomic absorption spectrometer. We used eggshells after hatching for the above two analyses.

Maternal attendance of eggs and neonates by a telemetered female was observed in a deciduous forest on Amamioshima Island. The female was surgically implanted with a radio-transmitter on 22 February 2007 (for methods see Reinert and Cundall 1982 and Nishimura et al. 1995) and was radio-tracked every month for one year.

Total shell mass	18.95	21.71	18.15	20.62	387	388	492	118	118	113	421	401
Calcium mass	0.22	0.40	0.15	0.27	42.56	50.89	63.85	10.55	11.16	10.92	34.06	29.34
Ca as % total	1.16	1.84	0.83	1.31	11.00	13.12	12.98	8.94	9.46	9.66	8.09	7.32

For the laboratory experiment, one of the three gravid females from Okinawajima was housed in a glass cage (600 × 300 × 350 mm) with shelter, water bowl, and artificial turf as substratum. Food (euthanized mice) was offered at 7–14 day intervals. On 23 August 2007 the female laid five eggs, two of which were infertile. The next day, we gently took out the eggs, using forceps, to measure their size, and immediately returned them to their original position. We then left the eggs undisturbed while recording maternal attendance of the eggs using a video camera (SONY DCR-TRV30, interval mode, 1.5 second / min), until the three live eggs hatched (26 August).

After hatching we conducted a experiment in which we moved neonates and mothers to observe whether they would re-aggregate every day from 1 to 11 days, except for days 4, 7, 9, and 10. Prior to the experiment, the shelter was removed, and the neonates were measured and painted on their dorsal parts for individual identification. Each day we moved the three neonates to one side of the cage and moved their mother to the other side. One hour after this manipulation, we recorded whether each neonate was in contact with the mother. It should be noted that we did not determine which individual(s) moved to re-establish proximity.

Results.—We observed hatching of a total of 22 eggs (from 7 clutches). Seven of the 22 eggs hatched on the day they were deposited. The longest incubation period was 4 days. The stage of embryos immediately after oviposition was 43 (last stage; Hubert and Dufaure 1968) in all eggs (Fig. 1). The proportion of the eggshells' area covered with calcium varied greatly both among and within clutches (proportion of calcium on each eggshell; clutch A: 0.80, 0.56, 0.17; clutch B: 0.46; clutch C: 0.98, 0.93). The percentage of calcium contained in an eggshell, by mass, was considerably lower in *O. okinavensis* than in the other three species (Table 1).

FIG. 2. A wild female *Ovophis okinavensis* attending eggs.

At 1102 h on 6 September 2007 we located the telemetered female coiled along a log on a forest floor, with its body partially concealed under the log. We initially detected the position of the snake from approximately 2 m away by the conspicuous movement of the snake, apparently in response to our approach. The female extended and raised its head and the anterior part of its body nearly vertically above the ground with frequent tongue flicking (> 1 / sec). After measuring several environmental variables, we left the site to avoid further disturbance. We visited the site again at 0030 h on 7 September and found the snake at the same spot. We slowly approached the snake and noticed a clutch of eggs under her body. A single loop of the posterior part of her body encircled the eggs, and her head and S-shaped body lay over the clutch (Fig. 2). As we approached more closely, she raised her head by extending the anterior part of the body and twitched the raised body repeatedly and intermittently in a peculiar manner while directing the head toward us, with frequent tongue flicking. We observed embryos inside two eggs through the partially transparent eggshells, and a third egg appeared to be infertile. When we returned to the site at 1500 h on the same day, we found the female at exactly the same spot, with three neonates (Fig. 3). Two of them were intertwined beside the female (at ca. 5 cm), and the other was concealed behind her body and under the log. The female showed the above-mentioned conspicuous twitching movement in response to our approach. After several minutes one of the exposed neonates slowly crawled behind the female. At 1532 h on 8 September we again confirmed her attendance of the neonates. For logistic reasons we did not have an opportunity to track the female again until 28 October, when the female was located alone approximately 85 m from the oviposition site.

Maternal attendance of eggs by the experimental female was observed at ovipostion. The video analysis demonstrated that the mother never left the eggs until all live eggs hatched. Her posture, however, changed several times. Incubation periods of the eggs varied from 1–3 days. Neonates that hatched earlier occasionally crawled around in the cage. While attending the unhatched eggs, the female often moved her head close to the neonates as they approached her. When we attempted to remove the eggs or neonates from the attending mother, we frequently observed that the mother elevated her head and followed the movement of the forceps with frequent tongue flicking, but she never struck them.

COLOR REPRODUCTION SUPPORTED BY THE THOMAS BEAUVAIS FUND

FIG. 3. A wild female *Ovophis okinavensis* (same individual as in Fig. 2) attending neonates. This photo was taken approximately 15 h later than Fig. 2.

In the relocation experiment, all three neonates and their mother re-aggregated at one and two days after hatching. Three and five days after hatching, two neonates and the female re-established their association. Six days after hatching, only one neonate re-associated with the mother, and the other neonates coiled side by side, away from their mother. Only the latter two neonates had opaque eyes. The neonatal ecdysis occurred seven and eight days after hatching. No maternal attendance was observed eight and eleven days after hatching.

Discussion.—This study confirms the short incubation period of *O. okinavensis* reported in previous studies (Koba 1959; Fukada 1964; Koba et al. 1970; Nishimura and Kamura 2000). Short incubation periods in snakes have been reported in *Liochlorophis vernalis* (4 to 23 days; Blanchard 1933), but the proportion of calcium contained in its eggshells (21.43% of total eggshell mass; Cox et al. 1984) is more than ten times higher than that of *O. okinavensis* (0.83–1.84%). Although our study is preliminary, considering the calcium-poor eggshells with variable quantities of calcium, it is possible that the eggshell of *O. okinavensis* is not as functional, in terms of providing protection, gas exchange, or water balance, as the eggshells of other animals. Moreover, because a short incubation period has often been interpreted as a stage in the transition from oviparity to viviparity (Packard 1966), the remarkably short incubation period and calcium-poor eggshells of *O. okinavensis* may be viewed as such an intermediate step. The phylogenetic position of *O. okinavensis* supports this interpretation because the most closely related species, *Trimeresurus gracilis*, as well as genera in their sister group including *Bothrops*, *Porthidium*, *Agkistrodon*, *Sistrurus*, and *Gloydius* are all viviparous (Malhotra et al. 2010). *Ovophis okinavensis* is thus a useful species from which to gain insights into the evolution of viviparity, or the possible reversal to oviparity (Lynch and Wagner 2010), among reptiles.

Our observations in the field and laboratory provide evidence of maternal attendance of neonates in an oviparous snake. Our laboratory experiment suggests that attendance of neonates may not be limited to immediately after hatching but may last until the first neonatal ecdysis, a typical phenomenon in pitvipers (Greene et al. 2002). Considering the incubation period and the fact that neonates and the mother re-aggregated after being moved, it is unlikely that the attendance of neonates in *O. okinavensis* simply reflects physiological stress of the mother immediately after oviposition or coincidental aggregation of adults and neonates. Instead, we suggest that the behavior represents active maternal care as also suggested by Fukada (1964) and Koba et al. (1970). The observed wariness of the females, which contrasts with the usual docile behavior of *O. okinavensis* (Takara 1962; Mori unpublished data), may suggest a guarding function of maternal attendance that increases survivorship of neonates. Ecological consequences of the short incubation period, calcium-poor eggshells, and maternal care in *O. okinavensis* deserve future investigation, which may enhance our understanding of the evolution of viviparity.

Acknowledgments.—We would like to express our sincere thanks to M. Saka for his generous instruction and assistance in measuring calcium. We also thank K. Mochida for his help in using NIH Image, H. Takahashi for field assistance, M. Toda for provision of a pregnant snake from Amamioshima and A. H. Savitzky for comments on the manuscript. This study was partially supported by a grant from the Japan Society for the Promotion of Science (18570019) and the Global COE Program (A06) to Kyoto University.

Breeding Phenology of *Leiopelma pakeka*: a Threatened Frog Never Found Breeding in the Wild

The timing of breeding is a relevant aspect of a species' biology (Blaustein et al. 2001; Gibbs and Breisch 2001), and may be particularly important information for those involved with conservation (Hocking et al. 2008; Jakob et al. 2003; Paton and Crouch 2002). Yet in two threatened species of leiopelmatid frogs from New Zealand, *Leiopelma hamiltoni* and *L. pakeka*, breeding has never been recorded in the wild (Bell 1996, 2008; Germano and Bishop 2007). However, the timing of breeding can be inferred from other information, such as sexual behavior and appearance of progeny in the wild or breeding events in captive frogs. Here, information on the breeding phenology of the Maud Island Frog, *Leiopelma pakeka*, is discussed (Fig. 1). This frog is nocturnal, terrestrial, independent of open water, and occupies retreat sites by day under rocks, logs and vegetative cover where breeding is likely to occur (Bell 1985; Fig. 2). It ranks among the top 100 amphibians on the EDGE list, being both evolutionarily distinct and threatened (Hitchmough et al. 2007; IUCN 2010; Newman et al. 2010; Zoological Society of London 2010). *Leiopelma pakeka* was initially regarded as *L. hamiltoni*, but was then described as a cryptic phylogenetic species based on comparison of allozyme and morphometric data (Bell et al. 1998). Studies of captive frogs have revealed the mode and timing of reproduction, with oviposition occurring in the late austral spring or early summer (Bell 1985,

BEN D. BELL
Centre for Biodiversity and Restoration Ecology
School of Biological Sciences, Victoria University of Wellington
PO Box 600, Wellington 6140, New Zealand
e-mail: Ben.Bell@vuw.ac.nz

Fig. 2. Habitat of *Leiopelma pakeka* on Maud Island. Photo by Ben Bell.

2010), however this may not represent the situation in the wild.

This study draws on information from captive breeding studies near Wellington, New Zealand, and from long-term demographic research on Maud Island (41.0167°S, 173.8833°E), central New Zealand (Bell et al. 2004; Bell and Pledger 2010; Newman 1990). First characterized by Stephenson (1961), *L. pakeka* survived only on Maud Island, probably because no invasive mammalian predators, such as rats or mice, have established there (Bell 1978). Demographic studies of *L. pakeka* on Maud Island over the past 35 years represent some of the longest population research on any wild anuran, revealing K-selected traits with some frogs living for up to 37+ years (Bell and Pledger 2010).

The only direct information on breeding in *L. pakeka* comes from captive frogs held in secure enclosures in mainland forest sites near Wellington in conditions resembling as closely as possible those in the wild (Bell 1978, 1985, 2008; Bell and Wassersug 2003; Lukis 2009). Here, *L. pakeka* (also *L. hamiltoni*) successfully bred in the austral spring/summer and individual females laid up to 19 eggs under rocks and logs in a terrestrial nest. Tadpoles are endotrophic (non-feeding) (Wells 2007) and exoviviparous, (following terminology of Altig and Johnston 1989), with the male undertaking care of the terrestrial eggs and hatchlings (Bell 1985, 2008; Bell and Wassersug 2003) (Fig. 3). Laying dates for captive *L. pakeka* were over October–December (Bell 1978, 1985). Eighty-seven *L. pakeka* progeny (from 19 broods) were reared to the end of metamorphosis, which occurred in late summer/fall (Figs. 4, 5). The mean ± SE snout–vent length (hereafter SVL) at the end of metamorphosis was 11.9 ± 0.1 mm (N = 87; range 10.0–13.2 mm).

After one year's growth in outdoor enclosures, the mean SVL ± SE of juvenile frogs was 18.1 ± 0.4 mm (N =16; range 15.5–20.2 mm). On average the SVL of captive juveniles increased from 11.9 to 18.1 mm in their first year. Assuming equivalent development, this information can be used to identify juvenile frogs of equivalent size in the wild on Maud Island. Over the period of long-term population study (1976–2010), 155 young frogs measuring 18 mm SVL or less were caught on the island, the smallest of them being 11.6 mm SVL (Table 1).

Most of the smallest frogs were found on Maud Island in the austral fall from March onwards, although a few small juveniles were caught as late as September (Table 1). The monthly mean SVL ± SE for the year commencing March shows a significant linear trend ($r^2 = 0.9517$, $p < 0.001$), indicating first emergence

FIG. 3. Captive adult male *Leiopelma pakeka* with hatchlings under log in outdoor enclosure. Photo by Ben Bell.

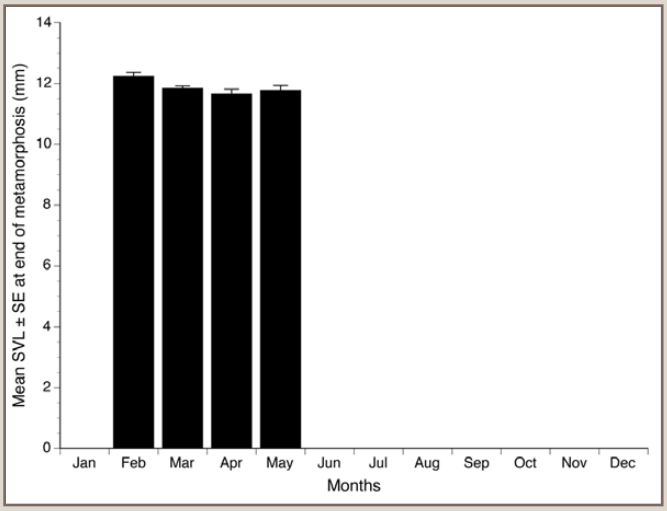

FIG. 4. The monthly distribution and mean SVL ± SE of 87 captive *Leiopelma pakeka,* at the end of metamorphosis. The frogs were bred and reared in outdoor enclosures sited under forest near Wellington. Sample sizes were February (N = 13), March (N = 49), April (N = 18) and May (N = 7).

FIG. 5. Captive-reared *Leiopelma pakeka* on 28 March 2008 at approximately 3.5 months of age, SVL 12.0–12.1. Metamorphosis is almost complete, with only small tail remnant present. Photo by Ben Bell.

TABLE 1. Monthly size distribution of 155 juvenile *Leiopelma pakeka* up to 18 mm SVL caught during a series of sampling sessions on Maud Island over the period 1976–2010.

of young juvenile frogs in the late summer or early fall (Table 1). The resulting regression (y = 0.483x + 11.780) over their first year predicts them growing to 17.6 mm by February. Percent seasonal mean SVL increases were: fall 10.9% (March–May); winter 6.6% (June–August); spring 12.5% (September–November); and summer 11.2% (December–February).

Direct evidence from captive breeding enclosures showed that *L. pakeka* breeds in the austral spring/summer (November–December), with offspring completing metamorphosis by late-summer or fall (February–May; Figs. 4, 5). The evidence from Maud Island presented here suggests little difference between the timing of breeding on the island and under the relatively natural regimes maintained for captive frogs (Bell 1978, 1985, 2008). The earliest reported juvenile *L. pakeka* on Maud Island was on 19 January 2010 (N. Mana, pers. comm.). Other terrestrial *Leiopelma* are also spring or summer breeders, captive *L. hamiltoni* breeding at about the same time as *L. pakeka* (Bell 1985), while Archey's Frog (*L. archeyi*) from warmer latitudes breeds a little earlier (October–November) both in the wild and in outdoor enclosures (Bell 1985; Thurley and Bell 1994). Terrestrial *Leiopelma* take at least 3.5 months to reach the end of metamorphosis (Bell 1978, 1985), so emergence of *L. pakeka* juveniles in the early fall (March–April) suggests breeding occurs there in late spring to early summer (November–December). They are K-selected species, like other terrestrial *Leiopelma*, with marked longevity, delayed maturity, small clutch size, and relatively infrequent breeding as compared to r-selected frogs (Bell et al. 2004; King et al. 2009). Breeding, growth and development depend on a range of abiotic and biotic factors, such as ambient temperature, phenotype, parental condition, and clutch size, so variation in their timing is to be expected, and this was the case (Fig. 4, Table 1). Despite the frogs being active throughout the year on Maud Island (pers. obs.), the juvenile growth rate was less (6.6%) in the cooler winter months (June–August) compared with other seasons (10.9–12.5%).

Germano and Bishop (2007) reported amplectic behavior in *L. pakeka* on Maud Island in December and January, while Lukis (2009) also reports summer amplexus of *L. pakeka* in captive enclosures in Zealandia (Karori sanctuary, Wellington) at about the time they bred there. These observations of amplexus suggest enhanced summer sexual activity in wild and captive populations, and lend support to summer breeding on Maud Island. In contrast, Germano et al. (2010) and Germano (2010) report that testosterone metabolites in male *L. pakeka* and estrone and progesterone metabolites in females were at their peak during winter for both wild and captive frogs, while the greatest proportion of females with large ovarian follicles also occurred in the winter. The reason for urinary hormonal levels in the population peaking well before likely summer breeding remains unclear, and is an unexpected but interesting issue that needs resolution. While much has been learned about the breeding biology of these threatened and evolutionarily distinct frogs, there is still more to discover, including unraveling this apparent paradox.

Acknowledgments.—As *Leiopelma* species are protected in New Zealand under the Wildlife Act 1953, the study was undertaken under Government permits, initially from the former NZ Wildlife Service and more recently from the NZ Department of Conservation, while the Victoria University of Wellington Animal Ethics Committee gave additional approvals for the research. I am indebted to all those who have assisted in the frog studies on Maud Island, especially Don Newman for encouraging continued use of his 1976–1983 study plots, Charles Daugherty for help in the initial stages, and the many night searchers who have helped me over many years. I also thank Department of Conservation staff for their valued assistance and hospitality on Maud Island, and Victoria University of Wellington, Ace Doors Ltd., the Declining Amphibians Taskforce, and the Watson Trust for research funding.

Cover Images for *Herpetological Review*

We are looking for photographic images to appear on future covers of *HR*. To be considered, preferred images should have the following qualities:

- Should be technically superior photographs (e.g., composition, lighting, etc., should be excellent; subject must be in focus).
- Should be taken in vertical format, or, if in landscape format, permit cropping to achieve a vertical orientation (773 x 1000 ppi).
- Should be based on film or digital media; if the latter, the native resolution must be sufficiently high to permit cropping and/or enlargement to print publication quality.
- Preference will be given to images that depict poorly known species. These could include recently described taxa or species for which a color illustration has never been published.
- Preference will be given to images that communicate some aspect of the biology of the organism (e.g., predation, feeding, courtship, crypsis).
- Images should not have been published previously nor concurrently submitted for publication elsewhere (print or electronic media).

Images for consideration should be submitted as low-resolution jpg or pdf files. Do not send full resolution images unless requested to do so. All submissions or questions should be directed to the Editor (herpreview@gmail.com).

Taxonomic Implications of Color Pattern and Meristic Variation in *Aspidoscelis burti burti*, a Mexican Whiptail Lizard

The gonochoristic whiptail lizard *Aspidoscelis burti burti* is restricted to the vicinity of Guaymas on the coast of Sonora, México (Duellman and Zweifel 1962), near the southern limits of the Sonoran Desert (Brown and Wright 1994:70, map). Color-pattern characters, the diagnostic basis for taxonomic recognition of this form, were summarized by Duellman and Zweifel (1962:174) as follows: "Typically a five- or six-lined lizard with relatively indistinct spotting developing in the dark fields only of largest individuals." This brief description of the only member of the *A. sexlineata* species group in the Guaymas vicinity, coupled with Duellman and Zweifel's (1962:175) opinions on the significance of color pattern variation in four individuals of *Aspidoscelis* from the Sierra Tetalejo about 48 km south of Hermosillo, Sonora, and one from about 8.0 km north of Hermosillo, have constituted the only documentation for decisions on the taxonomic status of the *A. burti* complex in Sonora and the United States for nearly half a century. Specifically, we refer to treatment of *Cnemidophorus burti* Taylor ("1936" [1938]), maximum SVL about 98 mm, and *C. sackii stictogrammus* Burger (1950), maximum SVL about 130 mm, as the subspecies *A. b. burti* and *A. b. stictogramma* (Duellman and Zweifel 1962; Reeder et al. 2002; Wright 1993, 1994). This taxonomic arrangement has persisted though Duellman and Zweifel (1962:176) in reference to the aforementioned specimens also stated "Although we are calling these intermediate lizards intergrades, it is probable that they represent a population of sufficient constancy to deserve taxonomic recognition." Herein, we provide analyses and expanded descriptions of color pattern variation in what is presently known as *A. b. burti* (Tables 1–2) and *A. b. stictogramma*, complemented with meristic comparisons (Table 3). We also discuss the implications of these findings, supplemented with reassessment of variation in specimens treated as intergrades by Duellman and Zweifel (1962) and those misidentified by Good and Wright (1984), on the taxonomy of the *A. burti* complex in Sonora and the United States.

In addition to specimens in the University of Arkansas Department of Zoology (UADZ) collection maintained by JMW, we used online and curator-assisted searches of museum databases with large holdings of whiptail lizards from Sonora and Arizona to secure loans of specimens relevant to an ongoing assessment of the taxonomic relationships of the *Aspidoscelis burti–stictogramma–costata* complex. For this study, we selected a total of 156 specimens from seven institutions (Appendix I), including taxa and putative intergrades in the *A. burti* complex (sensu Duellman and Zweifel 1962).

Meristic characters analyzed (terminology after Burt 1931; Smith 1946; Walker 1981a,b; Table 1) included counts of (1) granules (= scales) at midbody from the right outer row of ventral scales over the body to the left outer row of ventral scales (GAB), (2) dorsal granules longitudinally from the occipital scales to the first row of caudals (OR), (3) granules between the

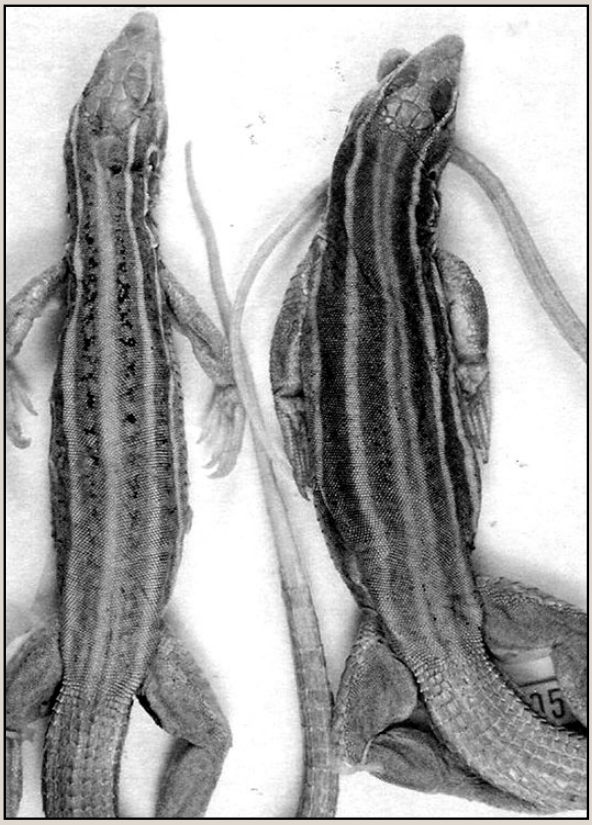

FIG. 1. Mature adult dorsal patterns in spotted five- and unspotted six-striped males of *Aspidoscelis burti* from 1.6 km W San Carlos Bay, Guaymas, Sonora, México (L: UADZ 453, 89 mm SVL; R: UCM 27055, 87 mm).

paravertebral stripes at midbody (PV; only possible for lizards with six stripes at midbody), (4) percent of granules around midbody between paravertebral stripes (PV/GAB × 100; only possible for lizards with six stripes at midbody), and (5) femoral pores (FP, summed from both sides). Scutellation characters qualitatively referenced included (1) anterior extent of the circumorbital scale series between the supraocular and median head scales, (2) size of the postantebrachial scales on the posterior part of each lower arm, and (3) size of the mesoptychial scales bordering the edge of the gular fold. Each specimen of the *Aspidoscelis burti* complex was sexed (via inspection of femoral pores, cloacal region, and/or internal organs), and its snout–vent length (SVL) measured to the nearest mm.

We used JMP v. 8 (SAS Institute, Cary, NC) to generate a mean ± 1 SE for each univariate meristic character, SVL for each sex, and population sample (Tables 1–3). For overall models that were statistically significant, we used Tukey-Kramer post-hoc comparisons to determine which means differed from the others. This procedure preserves alpha in statistical comparisons of multiple means (Sokal and Rohlf 1981).

Based on the smallest specimens examined (e.g., CAS-SU 16609 ♀, 53 mm SVL; UCM 27059 ♀, 57 mm SVL), we infer that juveniles of *Aspidoscelis b. burti* have a black to black–brown dorsal background color (paler near the ventral scales) that is divided into fields by either five or six light-colored longitudinal stripes. All specimens from CAS (N = 10), UADZ (N = 3), and UCM (N = 45) have pairs of white, cream, or buff-colored lateral stripes (one on each side from below the eye to the hind limb) and dorsolateral stripes (one on each side from above the eye to the base of the tail). A lizard becomes six-striped only when deposition of dark background color longitudinally separates a pale-tan middorsal band into two narrowly spaced paravertebral stripes from the parietal scales to the base of the tail. The five-striped pattern obtains when the paravertebral separation process does not occur; it is not a result of fusion of pre-existing stripes as stated by Duellman and Zweifel (1962:174). We recorded dorsal patterns in *A. b. burti* as six-striped (1) if the paravertebrals were visibly separated, even if by only one or two dark-colored scales (e.g., UCM 35410 ♂, 90 mm SVL), and (2) if the paravertebrals were only intermittently separated (e.g., Brown and Wright 1994: plate X–A; UCM 27072 ♀, 60 mm SVL). A hint of six incipient stripes was detected within a 2–5-mm area near the base of the tail in some five-striped *A. b. burti* (e.g., Fig. 1).

Whether five- and six-striped dorsal patterns in *Aspidoscelis b. burti* are examples of sexual, ontogenetic, or individual variation has not been assessed. The UCM sample of 45 specimens (14 female, 31 male) of this form from near Guaymas comprises these relative numbers of five- and six-striped phenotypes: 8:6 for females, 13:18 for males, or 21:24 for both sexes. None of these combinations deviates significantly from a 1:1 ratio, indicating that stripe number in *A. b. burti* is not sexually dimorphic. Moreover, stripe number is not an example of age/body-size dependent variation in *A. b. burti* (Tables 1–2). Sexual dimorphism in SVL is apparent for both five- and six-striped specimens in the 1964 and 1967 UCM samples of *A. b. burti* (N = 23 and 22, respectively; the latter with significantly larger SVL); however, the ratios of stripe numbers do not differ significantly (Table 2). Although stripe number in *A. b. burti* does not change ontogenetically, stripe appearance can change. A "faded" dorsal pattern is observed in large/old adults as increasing paleness of the lateral and dorsolateral fields, loss of contrast between stripes and fields, progressive loss of definition of spots (if present) in the dark fields, and blending of the background color of the hind limbs and tail to uniform gray–tan (Fig. 1). Unbroken stripes persist even in the largest adults of both sexes of *A. b. burti* (e.g., CAS 53425 ♂, 98 mm SVL; CAS-SU 15498 ♀, 86 mm SVL); however, stripe replacement by fragmentation/spot formation occurs during ontogeny in *A. b. stictogramma* in Sonora, México, and Arizona and New Mexico, USA (e.g., Brown and Wright 1994; color plate X–B; Zweifel 1959; plate 46–3; Fig. 2).

We sought to determine the extent to which spotted and unspotted dorsal patterns in *Aspidoscelis b. burti* vary sexually, ontogenetically, and individually. The 1964 UCM sample (N = 23) comprises seven gravid females (57–72 mm SVL) and 16 adult males (64–89 mm). Three of four of the five-striped females (65–70 mm) have distinct spots in the upper lateral and dorsolateral fields (= the fields) and one (71 mm) is unspotted; the three six-striped females (57–72 mm) are unspotted. Among the seven five-striped males (64–84 mm) from 1964, only three (73–81

mm SVL) have spots (all indistinct) in the fields; all nine six-striped males (68–89 mm) are unspotted. The 1967 UCM sample (N = 22) of *A. b. burti* comprises seven gravid females (67–83 mm) and 15 adult males (69–92 mm). Two of four of the five-striped females (67–78 mm) have distinct spots in the fields and two (78–83 mm) are unspotted. Two of three of the six-striped females (70–71 mm) in the sample have spots and one (70 mm) does not. Three of six of the five-striped males (73–90 mm) from 1967 have indistinct spots in the fields and two (84–90 mm SVL) have distinct spots. Four of nine of the six-striped males (75–83 mm) have distinct spots in the fields (e.g., Duellman and Zweifel 1962; plate 29 [1]; Fig. 1, this study), two (90–92 mm SVL) have indistinct spots, and three (69–86 mm) are unspotted (e.g., see Wright 1993:41; *A. b. burti* Fig. 7F). Although the mean SVL of 15 males (82.9 ± 1.8, 69–92 mm) from the 1967 UCM sample of *A. b. burti* is significantly larger ($P = 0.05$) than that of 16 males (76.9 ± 1.7, 64–89 mm) from the 1964 sample, development and definition of spots are not unambiguously age/size dependent (Table 1). Among eight of the 1964 males (79–89 mm), only two (25.0%) have spots, whereas among 11 of the 1967 males (80–92 mm), eight (72.7%) have spots. Our data support the following assertion by Duellman and Zweifel (1962:174) "…relatively indistinct spotting developing in the dark fields only of largest individuals" for *A. b. burti* (Table 1). However, the occurrence of similarly sized large lizards with and without spots indicates that spot development is not entirely deterministic. The small number of females available for study prevented us from testing whether the occurrence of spots was a form of sexual dimorphism in *A. b. burti*.

To identify diagnostic characters for *Aspidoscelis b. stictogramma*, we analyzed color pattern, meristic characters, and scutellation in 16 females (SVL = 88.9 ± 4.0, 66–115 mm) and 17 males (SVL = 107.1 ± 5.1, 62–130 mm) from the Santa Catalina Mountains, Pinal County, Arizona, from OMNH (Appendix 1). We selected specimens from this population because it is well removed from other closely related congeners: at least 150 km east of *A. xanthanotha* in the Ajo Mountains, Organ Pipe Cactus National Monument, Pima County, Arizona, and 400 km north of *A. b. burti* and *A. costata griseocephala* in Sonora. We also examined 32 specimens of *A. b. stictogramma* from Cochise Stronghold Campground, Coronado National Forest, Cochise County, Arizona, from UADZ (Appendix 1). Variation in UADZ sample was similar to that observed in the OMNH Pinal County sample. The largest males and females of *A. b. stictogramma* among the 33 OMNH specimens from Arizona and the 14 UCM specimens from central Sonora are more than twice the body size of those of *A. b. burti* from southern Sonora (Fig. 2). Each of the OMNH specimens has either six primary stripes (= pairs of laterals, dorsolaterals, and paravertebrals) or the ontogenetically derived remnants thereof; most of these specimens also have a very faint vertebral stripe. Among the 16 females, four have no vertebral stripe (66–105 mm SVL), three have an incomplete faint vertebral stripe (68–75 mm), and nine have a complete indistinct vertebral stripe (75–115 mm). All of the 17 males (62–130 mm) in the OMNH sample either have an indistinct vertebral stripe or its ontogenetic remnants. Among the females of *A. b. stictogramma*, five have stripes and developing spots in the fields (66–87 mm), five have stripes with distinct spots (73–95 mm), and six have partially fragmented stripes along with extensive spotting middorsally and vertical bars laterally (100–115 mm). Among the males of *A. b. stictogramma*, three have stripes with developing spots in the fields (62–68 mm), three have stripes and distinct spots (105–116 mm), and 11 (105–130 mm) have either partially (N = 4) or completely (N = 7) fragmented stripes, extensive spots middorsally and laterally, and bars laterally. Male-biased sexual dimorphism in SVL and in ontogeny of color pattern (males have complete replacement of stripes by spots and bars) is evident in the OMNH and UADZ samples of *A. b. stictogramma*, as is individual variation in color pattern in specimens of similar size in both sexes. Large adults of *A. b. stictogramma* in the UCM sample from central Sonora also have dorsal patterns of spots and stripe fragments (Fig. 2A and B).

Aside from the distinctive color patterns described (as well as significant differences in PV and PV/GAB; Table 3), there are no meristic or scutellation characters that distinguish *Aspidoscelis b. burti* and *A. b. stictogramma* in the context of variation in their clade within the *A. sexlineata* species group (Reeder et al. 2002). We detected a significant difference between these forms in the GAB; however, broadly overlapping ranges render assignment of a given specimen to one of the two subspecies on this basis unreliable. Similarly, only characters of color pattern separate all populations of *A. costata* and *A. gularis* (including *A. septemvittata*) from these taxa. Furthermore, Dessauer and Cole (1989) showed strong similarities in allozymes of *A. b. stictogramma* and *A. costata griseocephala* (i.e., genetic distance; 0.133 [Rogers 1972] and 0.110 [Nei 1972]).

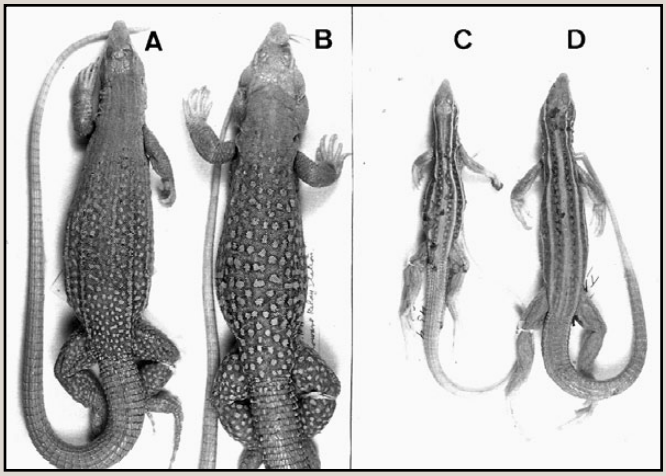

Fig. 2. Comparisons (photographed at same settings) of size and adult dorsal color pattern in specimens of *Aspidoscelis stictogramma* from 80 km N of Hermosillo on México Hwy 15, Sonora, México (A: UCM 35428 ♀, 118 mm SVL; B: UCM 35424 ♂, 124 mm) and *A. burti* from 1.6 km W San Carlos Bay, Guaymas, Sonora, México (C: UADZ 454 ♀, 84 mm; D: UADZ 453 ♂, 89 mm).

TABLE 3. Data for meristic characters (see text for definitions of abbreviations) for *Aspidoscelis burti* from Sonora, México (data except for OR are from Duellman and Zweifel 1962), *A. stictogramma* from Arizona, USA, and Sonora, and *A. stictogramma* ssp. from Sonora. Data are mean ± SE (first row) and N and (range) (second row); means for a character with one or more superscript letters in common are not significantly different.

We provide the first reassessment of color-pattern variation and its significance in the four AMNH specimens discussed by Duellman and Zweifel (1962) bearing on the taxonomic status of *Aspidoscelis b. burti*. Included are two lizards that either have six stripes (AMNH 80599 ♀, 78 mm SVL) and spot/fragment remnants thereof (AMNH 80601 ♂, 104 mm) or five stripes (AMNH 80602 ♂, 101 mm) and spot/fragment remnants thereof (AMNH 80600 ♂, 82 mm SVL). Duellman and Zweifel (1962) regarded the five-striped condition in AMNH 80600 and 80602 to be indicative of intergradation between *A. b. burti* and *A. b. stictogramma*, notwithstanding the fact that the specimens are very similar to *A. b. stictogramma* in all other aspects, including ontogenesis of dorsal color pattern from stripe dominated to total disruption of stripes. The intergradation hypothesis is problematic for these specimens because no population of the "nominal form" has been discovered within the nearly 50-km hiatus between the vicinity of Guaymas and the source population of the specimens, despite repeated efforts to identify one by T. P. Maslin (UCM), C. H. Lowe (UAZ), and J. W. Wright (UAZ, LACM). Thus, determination of past secondary intergradation between these forms must await formal tests using molecular techniques on samples from the relevant areas of Sonora.

We provide a description and discussion of six lizards (LACM 121421–26) with distinctive color patterns from 8.0 km south of Hermosillo, an intermediate area between the localities for the AMNH and UCM specimens, which were designated as possible intergrades between *A. b. burti* and *A. b. stictogramma* by Duellman and Zweifel (1962). If these specimens were in fact intergrades, the LACM specimens would be expected to have the unusual pattern variability seen among hybrids (e.g., Dessauer et al. 2000 [*Aspidoscelis tigris* complex]; Walker 1981a,b [*A. gularis* complex]), based on their provenance (Duellman and Zweifel 1962). However, they exhibit the uniformity typical of a single taxon, which they may well represent. Four of these lizards (LACM 121421–23, 121426) were misidentified as *A. b. burti* and used in allozyme analyses to identify the gonochoristic species involved in the hybrid origin of triploid parthenogenetic *A. exsanguis* (Good and Wright 1984). In fact, the LACM sample is at the opposite end of the spectrum from *A. b. burti* in color-pattern variation in the context of variation within the *A. burti* complex (compare Figs. 1 and 2 with 3). One lizard (Fig. 3A, LACM 121421 ♀, 74 mm SVL) has six stripes running most of the length of the body; however, the paravertebral stripes are in contact on the neck and indistinct spots are present in the dark fields. Another specimen (Fig. 3B, LACM 121423 ♂, 78 mm) has six completely separated stripes and a profusion of sharply defined spots/bars, some of which contact the stripes. In the other four male LACM specimens, the stripes have been replaced by distinct gray–white spots middorsally and spots and bars laterally. Among these, the positions of spots/fragments in the former positions of the paravertebral stripes indicate that the stripes were completely separated (i.e., six striped) as juveniles in two specimens (Fig. 3D and F, LACM 121425, 102 mm and LACM 121422, 102 mm, respectively), whereas two had incompletely separated paravertebral stripes on the neck as juveniles (Fig. 3C and E, LACM 121426, 82 mm and LACM 121424, 100 mm, respectively). We did not find evidence of intergradation in color pattern between specimens of *A. b. burti* and *A. b. stictogramma* from Sonora, as had been asserted without supporting data by Wright (1994:260).

Treatment of *Aspidoscelis b. burti* and *A. b. stictogramma* as subspecies for the past 47 years was based on fragmentary data and the tentative identification of five specimens from north (UCM 8605) and south (AMNH 80599–602) of Hermosillo

TABLE 4. Comparison of taxonomic arrangements of the *Aspidoscelis burti* (formerly *Cnemidophorus burti*) complex.

Author(s) Taxa Recognized	Based on Original Data
Duellman and Zweifel (1962); Reeder et al. (2002)	Yes
Aspidoscelis burti burti	
Aspidoscelis burti stictogramma

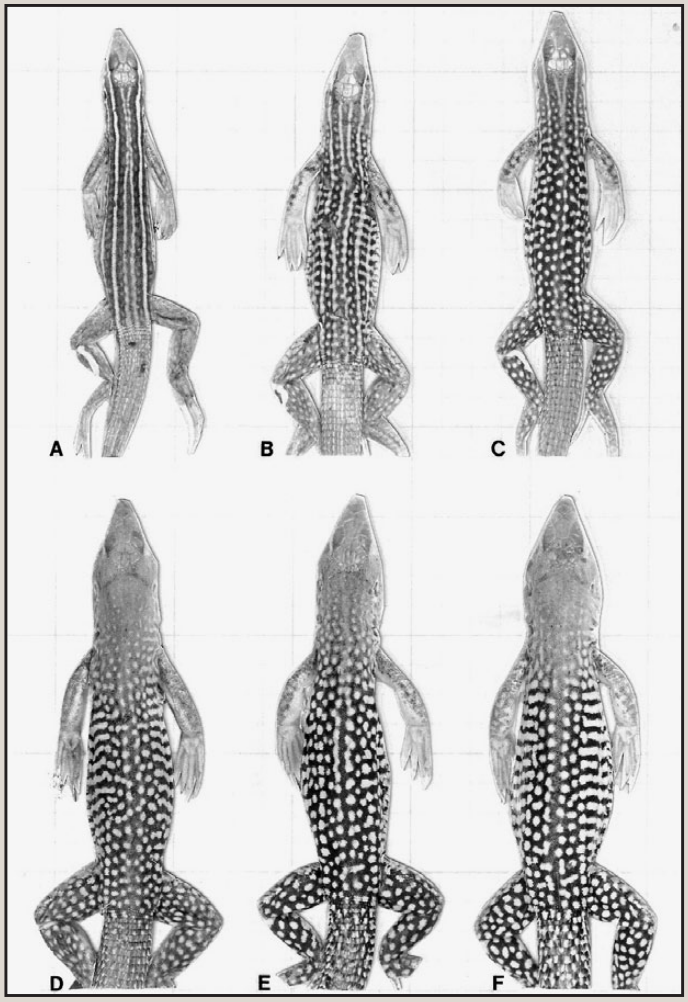

FIG. 3. Variation in dorsal color pattern of a sample (all males except LACM 121421) provisionally allocated to *Aspidoscelis stictogramma* from Cerro de la Agualurca, 8.0 km S of Hermosillo, Sonora, México (A: LACM 121421, 74 mm SVL; B: LACM 121423, 78 mm; C: LACM 121426, 82 mm; D: LACM 121425, 102 mm; E: LACM 121424, 100 mm; F: LACM 121422, 102 mm).

as intergrades (Duellman and Zweifel 1962). The assertions of Wright (1993, 1994), who supported recognition of these forms as subspecies reportedly based on new information on intergradation, were not documented by localities, voucher specimens, or data on variation. We requested this information and offered this manuscript to Wright, but received no response to our queries. Consequently, we are compelled to dismiss his statements concerning the taxonomic status of these subspecies given the absence of supporting data.

We regard *Aspidoscelis burti*, *A. stictogramma*, and *A. xanthanota* as the northwestern-most cluster (see Moritz et al. 1989; Fig. 1) of derivatives from a prototype from which some southern Sonoran populations acquired the potential for development of five-striped dorsal patterns. Of these, *A. burti* (restricted to a small area of coastal Sonora) and *A. xanthanota* (sensu Collins 1991; see Wright 1994; color plate X–C) (restricted to a small area in Arizona and possibly adjacent Sonora) represent peripheral isolates. A reviewer of this report opined that *A. burti* and *A. xanthanota* could be smaller-bodied populations derived from *A. stictogramma* as an alternative hypothesis for their origins. *Aspidoscelis burti* is an unusual member of the complex in having four identifiable variants: five stripes with and without spots and six stripes with and without spots. Nevertheless, *A. b. stictogramma* is at once the most divergent and widely distributed member of the complex, based on the combination of giant size (maximum SVL ca. 130 mm) and complete ontogenetic loss of stripes in males.

The search for an appropriate taxonomic treatment of the *Aspidoscelis burti* complex has resulted in several sets of answers (Table 4). Wright (1994) mentioned that extensive intergradation between *A. b. stictogramma* and *A. costata griseocephala* (sensu Zweifel 1959) occurs in southern Sonora; however, he did not present precise localities, specimens examined, and/or morphological data in support of his use of the name *A. burti griseocephala*. Pending publication of such information, there is no basis for altering the name combination *A. costata griseocephala* (see Reeder et al. 2002). The first departure from Duellman and Zweifel's (1962) taxonomic arrangement for the *A. burti* complex was proposed by Collins (1991), who justified his nomenclatural changes primarily on philosophical grounds. He invoked the evolutionary species concept, emphasizing apparent allopatry from other members of the complex and presumed diagnosability, to elevate *A. b. xanthanota* Duellman and Lowe (1953), as well as numerous other subspecies of amphibians and reptiles, to species rank. Many of Collins's (1991) recommendations have been adopted in checklists of North American amphibians and reptiles by Collins and Taggart (2009) and Crother (2008). By listing the combination *A. b. stictogramma*, these authors tacitly accept

Duellman and Zweifel's (1962) recommendations on the status of *A. b. burti* in Sonora. If zones of secondary intergradation (or hybridization) do exist between members of the *A. burti* complex, as reported for *A. tigris aethiops* and *A. tigris punctilinealis* (= *Cnemidophorus tigris gracilis*) in north–central Sonora by Taylor and Walker (1991), they have yet to be located/reported. At present, those applying either the biological or evolutionary species concept would be justified in recognizing three species: *A. burti* (monotypic), *A. stictogramma* (potentially polytypic), and *A. xanthanota* (monotypic) based on the data presented herein.

Acknowledgments.—We are grateful to the following individuals for the opportunity to examine specimens of *Aspidoscelis* in their care (acronyms after Leviton et al. 1985): C. Cole (AMNH); R. Drewes (CAS, CAS-SU), D. Kizirian and K. Beaman (LACM), L. Vitt (OMNH), G. Bradley (UAZ), and S.-K. Wu (UCM). We thank the Arizona Game and Fish Department and Forest Service, U. S. Department of Agriculture, for providing scientific permits for acquisition of UADZ specimens of *A. stictogramma* referenced in this report. Special appreciation is extended to C. Cole, T. Reeder, and H. Taylor for critically reading earlier versions of the manuscript, without specifically endorsing any part of it, and to R. Espinoza and R. Hansen without whose editorial expertise we could not have reached our publication objectives.

Aspidoscelis stictogramma (N = 79). ARIZONA. Cochise County: UADZ 7212, 7264, 7268, 7271, 7300–04, 7874–78, 7996–006, 8083–84, 8143–44, 8453–54, 8511: Cochise Stronghold Campground, Coronado National Forest. Pinal County: OMNH 38806–38: Bonita Wash, Windmill Camp, bajada of Santa Catalina Mountains (32º 33.68' N, 110º 40.453' W, 1333 m). MEXICO. Sonora: UCM 35423–33: 80 km N of Hermosillo on México Hwy 15; UCM 42047–49: 45 km W of Santa Ana.

Aspidoscelis stictogramma subsp. (N = 19; includes AMNH and UCM specimens identified as *A. burti burti* x *A. burti stictogramma* by Duellman and Zweifel 1962; LACM specimens identified as *A. b. burti* by

Good and Wright [1984], and newly reported UAZ specimens). MEXICO. Sonora: AMNH 80599–602: 8.0 km SE of La Pintada about 48 km S of Hermosillo; UAZ 6657–58: Sierra Tetalejo (ca. 8.0 km S of La Pintada); LACM 121421–26: Cerro de la Agualurca, 8.0 km S of Hermosillo; UCM 8605: 8.0 km N of Hermosillo; UAZ 6681–82: Tetavejo (archeological cave site); UAZ 6684, 6686, 6688: 22.1 km S of El Oasis (49.6 km N of Hermosillo); UAZ 6687: 49.9 km N of Hermosillo.

APPENDIX 2
Distinguishing characters of *Aspidoscelis burti* prepared from UCM 27051–73, 35401–22 (N = 45)

Black to black–brown dorsal ground color, five (N = 8 ♀ and 13 ♂, 46.6%) or six (N = 6 ♀ and 18 ♂, 53.3%) pale colored dorsal stripes, spots present (N = 7 ♀ and 14 ♂ , 46.6%) or absent (N = 7 ♀ and 17 ♂, 53.3%) in the upper lateral and dorsolateral fields, stripes persistent throughout life (N = 45, 100%), contrast between fields, stripes, and spots (if present) diminishing with age to produce a faded appearance, venter without a dark suffusion, circumorbital scale series ending posterior to frontal scale, enlarged postantebrachial scales, enlarged mesoptychial scales, 93.3 ± 1.4 granules around midbody, 198.3 ± 3.7 granules from occiput to first row of caudals, 1.5 ± 0.4, granules between the paravertebral stripes at midbody, 34.0 ± 0.7 femoral pores (summed), and 98 mm maximum SVL in males.

APPENDIX 3
Distinguishing characters of *Aspidoscelis stictogramma stictogramma* prepared from OMNH 38806–38 (N = 33)

Black to brown dorsal ground color, six (9.0%) or 7 (91.0%, including an indistinct partial or complete vertebral) stripes, spots developing on stripes and in intervening dark fields early in life, females infrequently develop a dorsal pattern of stripe fragments and spots, males frequently develop a dorsal pattern of stripe-fragments, spots, and lateral bars, venter without a dark suffusion, 105.9 ± 1.0 granules around midbody, 212.3 ± 1.7 granules from occiput to first row of caudals, 7.5 ± 0.3 granules between the paravertebral stripes at midbody, 38.3 ± 0.4 femoral pores (summed), and 130 mm maximum SVL in males.

Microhabitat Use and Choice of Refuge in *Sceloporus magister*

Individual lizards often occupy multiple microhabitats during the course of a day, and thecurrent microhabitat may affect decisions regarding refuge selection (e.g., Cooper 1998; Cooper and Wilson 2007). The montane phrynosomatid lizards *Sceloporus virgatus* and *S. jarrovii* occupy rocks, ground, logs, and trees (Smith 1996) and vary aspects of their escape behavior and refuge selection among these microhabitats (Cooper and Wilson 2007). Here, I report variation in occupation of microhabitats and the effect of types of microhabitats on selection of refuges in a population of the Desert Spiny Lizard, *S. magister*.

Methods.—The abundance and ease of observation of *S. magister* in Rillito River Park in Tucson, Arizona provided an opportunity to make preliminary observations on substrates where they occur, microhabitats used as destinations or refuges after escape, and the effect of tree diameter on escape behavior by lizards perched low on trees. All observations were conducted on warm (30–36°C), sunny days in early June of 2009. Because lizards off paths in Rillito River Park are frequently exposed to people walking, running and bicycling on the paths, they often do not flee when people pass. However, they flee if approached directly. After sighting an adult lizard, I recorded its initial substrate and approached it directly at approximately 1 m/s until it fled. Sex was not ascertained. When lizards were on rocks or ground, I continued to approach until a lizard entered a refuge. For lizards initially on trees, I approached until the lizard climbed out of reach or moved off the tree onto ground. I also recorded the perch height and diameter of the tree at its ground level. Finally, I recorded the type of refuge used.

I used a chi-square test to examine differences in frequencies of occupation among the microhabitat types. For lizards initially on trees, I statistically examined relationships among perch height, tree diameter, and escape by climbing versus descending to ground. I conducted a regression of perch height on tree diameter, an analysis of variance of perch heights in lizards that fled up the tree or fled down and onto the ground, and an analysis of variance to assess the effect of tree diameter on climbing upward versus fleeing to the ground. Statistical tests were two-tailed with $\alpha = 0.05$. Effect sizes are given as n^2 for analysis of variance (Cohen 1992) and Cramer's V for chi-square (Gliner et al. 2002).

Results.—When initially sighted, 53 individuals were on the ground, 13 were on rocks, and 17 were on trees. Frequency of use varied significantly among these microhabitats ($\chi^2_2 = 35.77$, $P < 0.001$; $V = 0.46$). Lizards occupied ground significantly more frequently than rocks ($\chi^2_1 = 24.24$, $P < 0.001$; $V = 0.61$) or trees ($\chi^2_1 = 18.52$, $P < 0.001$; $V = 0.52$), but frequency did not differ significantly between rocks and trees ($\chi^2_2 = 0.54$, $P > 0.10$).

Refuges used by the lizards differed among initial microhabitats (Table 1). The proportions of the refuge types used for all lizards initially on ground or rocks pooled were 0.15 for trees, 0.27 for ground squirrel burrows, 0.55 for yucca, *Opuntia*, and bushes, and 0.03 for others. Among lizards not initially on trees, only 0.15 fled to trees, a much smaller proportion than remained on trees (Table 1). Lizards initially on trees were significantly more likely to flee up and around trees than were lizards initially in other microhabitats (pooled; $\chi^2_1 = 8.10$, $P = 0.0044$; $V = 0.31$).

	Rock (far side)	0.02 (1)
Rock		
	Bush, Yucca, or *Opuntia*	0.77 (10)
	Burrow	0.15 (2)
	Log	0.08 (1)
Tree		
	Ground	0.53 (9)
	Tree	0.47 (8)

For lizards on trees, the decision to escape by climbing upward versus fleeing to the ground was strongly affected by the diameter of the tree at its base ($F_{1,15}$ = 14.63, P < 0.0017; effect size: n^2 = 0.49). Variances of tree diameter did not differ significantly between refuge types (Levene's $F_{1,15}$ = 4.39, P > 0.05). The diameters of trees occupied by lizards that fled up and around trees were larger (0.30 ± 0.05 m, N = 9) than those of trees occupied by lizards that fled to the ground (0.11 ± 0.02 m, N = 8). Decisions by lizards on trees to flee to ground or climb higher were unaffected by initial perch height on the tree ($F_{1,15}$ = 0.22, P > 0.10), presumably because all lizards were initially low on trees (0–1.4 m). Variances were homogeneous (Levene's $F_{1,15}$ = 0.45, P > 0.10). Initial perch height and tree diameter were not significantly correlated ($F_{1,15}$ = 0.39, P > 0.10).

Discussion.—The more frequent occupation of ground than the other microhabitats by *S. magister* is likely a consequence of several factors., including the fact that that lizards engage in social activity and forage there, the lesser availability of the other substrates, and the availability of effective refuges, such as spiny plants and ground squirrel burrows, on the ground. The proportion of lizards on the ground (0.64) was much higher in *S. magister* than in *S. virgatus* or *S. jarrovii* (Cooper and Wilson 2007; Smith 1996). Surprisingly for a desert lizard, the proportion of individuals initially sighted on trees (0.20) in *S. magister* was similar to that reported for trees and logs in *S. virgatus* although it was lower than the proportion for *S. jarrovii* (Cooper and Wilson 2007; Smith 1996). Rocks were used by *S. magister* less frequently (0.16) than by the other species, at least in part because rocks are much less abundant at Rillito River Park than in the study sites in the Chiricahua Mountains.

I quantified only microhabitats used by *S. magister*. Because I did not record microhabitat availability, the findings do not bear directly on microhabitat choice. Microhabitat use varies geographically in *S. magister*, which is arboreal, saxicolous, or terrestrial (Johnson et al. 1948; Parker and Pianka 1973; Vitt and Ohmart 1974). Presumably, this variation is related to availability of the microhabitats themselves and of refuges therein.

Some of the differences in selection of refuges presumably were consequences of differences in availability of microhabitats among sites. For example, few rocks or bushes were near many of the trees, and rocks tended to be close to ground squirrel burrows, yuccas, and *Opuntia*. *Sceloporus magister* has a strong tendency to be arboreal, but is saxicolous or terrestrial where trees are scarce (Parker and Pianka 1973). Climbing out of reach in trees is a widespread trait in *Sceloporus* (Blair 1960; Cooper and Avalos, *in press*; Cooper and Wilson 2007), and may be expressed frequently by *S. magister* where trees are present. In the single population I studied, the lizards flexibly used whichever types of refuge were nearby.

All trees occupied by lizards were much taller than necessary for lizards to climb well above my reach, yet lizards selectively left smaller trees to seek refuge elsewhere, and climbed higher in larger trees. Because branch diameter decreases as height increases within trees, trees of smaller diameter may not have large enough branches to provide concealment when lizards climb out of immediate reach. When escaping up trees, lizards moved to the far side and stayed out of sight. Staying hidden on the far side may have been less feasible in smaller trees. If some terrestrial snakes and perhaps mammals climb trees to pursue lizards that can be seen when out of reach from the ground, escape to refuges off small trees might be safer than climbing. Another possible factor is that lizards high in smaller trees may be more detectible by and less able to escape from avian predators.

Acknowledgments.—Field work was conducted according to approved research protocol 00-037-06 of the Purdue Animal Care and Use Committee.

Plectrohyla hazelae (Taylor, 1940) Not Extinct

Plectrohyla hazelae, a stream-breeding tree frog from southern Mexico, has been reported in the past from several localities in the states of Oaxaca and Guerrero (Duellman 2001). Mendelson and Kabay (2009), however, demonstrated that all records of this species were in error or at least doubtful except for those from the area of the type locality. The type locality is on Cerro San Felipe in central Oaxaca a few kilometers north of the city of Oaxaca. This area is also known as the Sierra Aloapaneca. Mendelson and Kabay (2009) further stated that this species was last seen alive in 1975 and probably became extinct not very long after that year. The extinction of *P. hazelae* was earlier proposed by Lips et al. (2004).

Herein, we report recent sightings of this species at two different localities, both not far from the type locality. On 23 June 2003, we found two individuals in a dry streambed near the village of El Punto. The two males were calling at night from low bushes within pine-oak forest (Fig. 1). El Punto (17°20'N, 96°36'W) is located at 2000 m elevation on the eastern slope of Cerro San Felipe and was listed as a locality of *P. hazelae* by Duellman (1970).

On 7 May 2004, Moises Kaplan and the two authors collected tadpoles in a small creek near Ixtlán de Juárez; these were later described as those of *Plectrohyla hazelae* (Kaplan et al. 2006). Ixtlán de Juárez (17°20'N, 96°29'W) is located at about 1900 m elevation and 30 km N of El Punto. On 8 July 2004 we (PH and RA) returned to the same creek and found a small breeding colony of at least a dozen adults. Several males were calling at night from a patch of small broadleaf trees within pine-oak forest. Our observations suggest that *P. hazelae* reproduces at the beginning of the rainy season and that the metamorphosis of the young occurs also at this time of the year, which implies that the tadpole stage may last for about one year.

A female we found at the locality near Ixtlán is the first known female of this species (Fig. 2; Duellman 2001). It had a snout–vent length of 38.2 mm (largest known male 38.6 mm SVL; Duellman 2001). We did not observe any obvious differences in

FIG. 1. Adult male *Plectrohyla hazelae*, El Punto, Oaxaca, Mexico.

FIG. 2. Adult pair (female on left, male on right) of *Plectohyla hazelae* from Ixtlán de Juárez, Oaxaca, México. The female is the first example known for this species. The differences in coloration are not gender-based, instead reflecting individual variation. Individual frogs have the ability to change from light to dark green.

FIG. 3. Adult male *Plectrohyla hazelae* from El Punto, Oaxaca, showing dark ground color and light green spotting.

coloration between the genders except that the female's throat is heavily mottled with dark brown whereas in males the throat is pale yellow and immaculate. Males and females possess the ability to change their dorsal coloration between bright green and very dark green. The pale dorsal spots, which are characteristic of this species, are more pronounced when the frogs exhibit a dark ground color (Fig. 3).

Acknowledgments.—We thank Moises Kaplan for confirming the identification of frogs. Photo vouchers are deposited at the Amphibian and Reptile Diversity Research Center, University of Texas at Arlington: UTADC 6714 (Ixtlán de Juárez record), UTADC 6715, 6716 (El Punto record).

ART IN HERPETOLOGY

The illustration above originally accompanied an article titled "Monitor gouldi, Gould's Monitor Lizard," published in 1888 within the pages of *Prodromus of the Zoology of Victoria; or Figures and Descriptions of the Living Species of All Classes of the Victorian Indigenous Animals.* This periodical, published in twenty parts from 1878 to 1890 by the National Museum of Melbourne, was met with critical acclaim and wide popular support. John McCoy (1823–1899), director of the National Museum of Melbourne, wrote the text and employed a number of artists to illustrate his work, including John James Wild, the illustrator of this piece. Born in Switzerland in 1824, Wild traveled to Australia in 1881 where he was employed by McCoy to illustrate terrestrial and marine mammals for the *Prodromus.* Wild was noted for the clarity of his illustrations, his desire to depict his subjects in naturalistic environments, and his ability to fit an impressive amount of information onto a single page. All three of these characteristics are evident in this piece. Additional information can be found at: http://museumvictoria.com.au/caughtandcoloured/

Use of Fluorescent Visible Implant Alphanumeric Tags to Individually Mark Juvenile Ambystomatid Salamanders

Identification of individuals over time is essential for measuring growth, fecundity, survival, movement, and dispersal of amphibians. Such individual measures usually result in more robust estimates of processes affecting population growth and declines, and likely yield more effective management recommendations. There are a variety of marking and identification techniques that have been evaluated for use with amphibians including toe-clipping (McCarthy and Parris 2004; Otto and Scott 1999; Phillott et al. 2007; Waddle et al. 2008), passive integrated transponder (PIT) tags (Brown 1997; Gibbons and Andrews 2004; Otto and Scott 1999), coded wire tags (Sinsch 1997), radio-transmitters (Richards et al. 1994; Weick et al. 2005), pattern recognition (Gamble et al. 2008; Grant and Nanjappa 2006), various tattooing and branding techniques (Donnelly et al. 1994; Measey et al. 2001; Schlaepfer 1998), visible implant elastomer (VIE) marks (Grant 2008; Kinkead et al. 2006; Measey et al. 2001; Nauwelaerts et al. 2000; Ralston Marold 2001), and visible implant alphanumeric (VIAlpha) tags (Buchan et al. 2005; Gower et al. 2006; Heard et al. 2008; Measey et al. 2001). When selecting the most appropriate method, a researcher should consider impact on health and behavior of study animals, degree of invasiveness, ease and speed of use, handling time, mark longevity, expense, and number of unique marks necessary. Researchers should select tags or marking procedures with the least possible effect on behavior, growth, and survival.

Ambystomatid salamanders at metamorphosis are typically less than 40 mm SVL and weigh < 2 g (Petranka 1998). Their small size limits the practical options for individual identification of juveniles. Most individuals are too small for currently available internal radio-transmitters. Although Otto and Scott (1999) demonstrated that PIT tags could be surgically implanted in juvenile Marbled Salamanders (*Ambystoma opacum*) weighing from 2 to 4 g, ambystomatid salamanders in Missouri are typically closer to 1 g at metamorphosis (Osbourn, unpubl. data). In addition to the body size constraints of PIT tagging, the necessary surgical procedure requires extra time and precautions, limiting the ability to mark a large number of individuals. Recent advancements in pattern recognition technology are very promising (e.g., Gamble et al. 2008), however Marbled Salamanders, Spotted Salamanders (*A. maculatum*), and Ringed Salamanders (*A. annulatum*) lack their characteristic patterns at metamorphosis, limiting its effectiveness. Toe-clipping is limited by the number of possible combinations, regeneration, and potential harmful effects (Brown 1997; May 2004; McCarthy and Parris 2004). Though there is considerable debate about the potential harmful effects of toe-clipping versus the effects of other marking techniques (e.g., Funk et al. 2005; Phillott et al. 2007), it is likely that stress associated with increased handling time impacts animal health regardless of marking technique (Kinkead et al. 2006). Visible implant elastomers are very effective with most species. Although often sufficient for marking individuals, VIEs are limited by the number of possible combinations of mark colors and lightly pigmented marking locations (Heemeyer et al. 2007). Visible implant elastomers can also be inconvenient for fieldwork because of their tendency to become solidified and inoperative when inadequately refrigerated. Perhaps the greatest limitation of VIEs is their potential for misidentification due to tag migration. Misidentifications of VIE markings were reported for 19% of Western Red-backed Salamanders (Davis and Ovaska 2001), 17% of Eastern Red-backed Salamanders (Heemeyer et al. 2007), and 31% of Wood Frogs (Moosman and Moosman 2006). Ralston Marold (2001) did not observe VIE mark migration in stream

salamanders, however Bailey (2004) reported a misidentification rate of 13% in Blue Ridge Two-lined Salamanders which she attributed to color misidentifications, overlooking of small marks, and incorrect mark location.

Soft VIAlpha tags, manufactured by Northwest Marine Technology, Inc., are individually coded, biocompatible tags measuring 1.0 × 2.5 mm. They are imprinted with one letter (A–Z) and two numerals (00–99) on a fluorescent red, orange, or yellow background (also available as fluorescent lettering on black background or larger 1.5 × 3.5 mm tags, although these were not tested here). The combinations of colors and alphanumeric codes yield 7800 possible individual fluorescent tags. VIAlpha tags have been used extensively in fish (e.g., Frenette and Bryant 1996) and are increasingly being used for individual identification in a range of amphibian species (e.g., Measey et al. 2001; Pittman et al. 2008; Spickler et al. 2006). In contrast to PIT tags and similar to VIE marks, VIAlpha tags are inserted just below the surface of the skin and do not require deep insertion into the abdominal cavity. This comparably less invasive tagging procedure could translate into decreased handling and recovery times for small salamanders. For VIAlpha tags the problem of tag migration often reported for VIEs seems only to be a problem in amphibians with loose skin. Some studies examining VIAlpha tags effectiveness with frogs reported tag migration (Kaiser et al. 2009) or having to manipulate inverted tags through the skin with forceps so that they could be read (Heard et al. 2008; Kaiser et al. 2009). These problems have not been reported in species with tight connective tissue between skin and muscle such as salamanders and caecilians (Gower et al. 2006; Measey et al. 2001). We conducted an experiment to assess the effectiveness of VIAlpha tags for individual identification of juvenile ambystomatid salamanders by evaluating ease of application, readability, tag retention, and effect on body mass gained by individuals.

Materials and Methods.—We collected Marbled Salamander larvae (*Ambystoma opacum*) from the Daniel Boone Conservation Area, Warren County, Missouri, and raised them in 1000 L cattle watering tanks until metamorphosis. Juvenile salamanders were placed in individual 17 × 12 × 9 cm plastic containers with moist sphagnum moss and fed 4–5 crickets weekly. Prior to and during the experiment, salamanders were housed in a temperature controlled (24°C) animal care facility at the University of Missouri. A total of 59 individuals were randomly assigned to one of four treatments. Fourteen untagged and non-anesthetized salamanders served as the control, 15 were anesthetized without a tag, 15 were tagged without anesthetization, and 15 were tagged with anesthetization. Of the salamanders receiving tags, three colors (red, orange, and yellow) were used.

Tricaine methanesulfonate (MS-222) is an effective and commonly used anesthetic for sedating and immobilizing fish and amphibians (Lowe 2004). We chose a concentration of 500 mg/L of MS-222 based on the mass of our juvenile salamanders (Peterman and Semlitsch 2006). To achieve a neutral pH, we buffered the solution with 800 mg of $NaHCO_3$ (sodium bicarbonate) (Cooper 2003). Salamanders were placed in the MS-222 bath until anesthetized (unresponsive to prodding and unable to right themselves) and for no more than 5 minutes. Once anesthetized, individuals were rinsed of MS-222 by dipping them in a shallow dish of dechlorinated tap water.

We individually marked juvenile salamanders with Northwest Marine Technology (NMT), Inc., (Shaw Island, Washington, USA) VIAlpha tags. During the marking procedure, one investigator (MSO) inserted all VIAlpha tags to insure consistency, while three others monitored anesthetization, weighed and measured, and monitored recovery of individuals. Tags were placed subcutaneously under translucent epidermis near the lateral base of the tail (Fig. 1). We administered VIAlpha tags by first making a 1 to 2 mm incision with a sterile pointed scalpel blade and then used the injector provided by NMT to insert the tag approximately 3 mm inward from the entry wound. Non-anesthetized individuals were restrained by hand during tag injection. To minimize infection, we wore nitrile gloves and sterilized all equipment with alcohol before each injection. During the four weeks of monitoring, each salamander was removed from its container at weekly intervals, weighed with an electronic balance, and fed. The same observer (MSO) examined tags weekly for retention and assigned a ranking according to the following readability index: 0, tag not visible or not present; 1, tag visible but only color discernable; 2, tag color and partial code visible or incorrect code read; 3, correct code only read with use of blue LED light and amber filter glasses; and 4, correct code visible without aid of amber filter glasses. This index was a useful tool for determining whether readability and accuracy decreased over time. Tags were initially read without the use of aids and then read while using a blue LED light and amber filter glasses to examine the usefulness of the light and glasses.

We used two-way analysis of variance (ANOVA, SAS version 9.1) to test for significant differences between our treatment groups in proportion increase of body mass after four weeks.

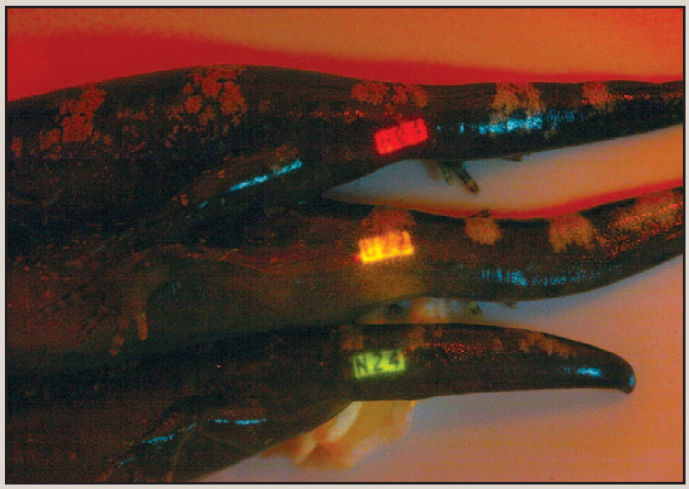

FIG. 1. *Ambystoma opacum* juveniles marked near the lateral base of the tail with VIAlpha tags as viewed with blue LED light and amber filter glasses.

TABLE 1. Mean initial body mass, mean final body mass, and mean proportion body mass increase (± SE) of Marbled Salamanders reared in the laboratory after being marked with VIAlpha tags and/or anesthetized with MS-222.

Treatment	N	Initial Mass (g)	Final Mass (g)	Proportion Mass Increase
Anesthetized	29	1.17	1.74	0.49 (± 0.15)
Non-anesthetized	29	1.25	1.80	0.46 (± 0.17)
Tagged	28	1.29	1.90	0.48 (± 0.14)
Non-tagged	30	1.13	1.63	0.47 (± 0.18)

To adjust for differences in mean initial body mass among our treatments, we used arcsine square-root transformed proportions. Anesthetization (anesthetized and non-anesthetized) and tag (tagged and non-tagged) treatments and their interaction (tag x anesthetization) were fixed effects in our model. We then used two-way ANOVA to test these same effects for significant differences in tag readability index scores after four weeks. Finally, we tested for random effects in tag retention and reading accuracy between anesthetized and non-anesthetized salamanders with a goodness of fit G-test (Zar 1999).

To supplement our laboratory experiment, we recorded additional observations on 122 Spotted Salamanders marked as recent metamorphs for ongoing mark-recapture experiments. Anesthetization, VIAlpha tagging procedures, housing, and care of these juveniles followed similar methods as in the laboratory experiment. After twelve weeks, our observer (MSO) assigned each salamander's tag a readability score and recorded tag retention. These additional observations were useful for examining tag retention over a longer time scale and comparing readability between species.

Results and Discussion.—The use of VIAlpha tags on small juvenile salamanders was successful. All tagged salamanders survived and grew during the four weeks of the experiment, although one small anesthetized untagged individual died after the first week. Our 100% survival of tagged individuals was comparable to the 96% survival of VIAlpha-tagged Pacific Treefrogs (*Pseudacris regilla*) reported by Buchan et al. (2005). Entry wounds created during tag insertion closed rapidly, lacked discoloration or swelling, and were typically considered healed within 24 hours. Our selected MS-222 concentration of 500 mg/L buffered with 800 mg of sodium bicarbonate was very effective, causing anesthetization in ~5 minutes with no detectable decline in health or behavior over four weeks. All surviving salamanders (N = 58) consistently fed and grew during the four-week period, increasing their mass by an average of 48%. There were no significant differences in the proportion of mass increase between tagged and untagged individuals ($F_{1,54} = 0.03$, $P = 0.869$), anesthetized and non-anesthetized individuals ($F_{1,54} = 0.009$, $P = 0.621$), nor was there an anesthetization by tag interaction ($F_{1,54} = 0.030$, $P = 0.3681$; Table 1).

Through experience tagging over 2000 juvenile Spotted Salamanders (*Ambystoma maculatum*) and Ringed Salamanders (*A. annulatum*) in the field, we have observed the advantages of VIAlpha tags and potential problems which can arise during tag injection. The effectiveness of VIAlpha tags appears to be primarily limited by the skill and experience of the operator. Although tedious and requiring some initial practice to use efficiently, VIAlpha tags can be individually loaded in approximately 10 sec and injected into properly immobilized salamanders in less than 15 sec by a lone operator in the field. After a 5 min anesthetization period, handling time is often no more than 20 sec for immobilized salamanders. A recovery period of 10 to 20 min is also needed for anesthetized individuals. Our VIAlpha marking procedure time for juvenile salamanders is very similar to caecilians (< 1 min plus anesthetization and recovery; Measey et al. 2001) and Pacific Treefrogs (< 15 sec with no anesthetization; Buchan et al. 2005). Marking procedure times for VIAlpha tags are very similar to VIEs. Ralston Marold (2001) reported that it took 30 sec to inject four VIE marks and the entire procedure, including anesthetization and recovery, took about 20 min per individual. The VIAlpha tagging procedure can be streamlined with one technician loading tags and anesthetizing batches of five or more individuals while a second technician simultaneously injects and measures others.

Attempting to inject tags into improperly restrained individuals can result in agitation and tearing in the entry wound, potentially affecting tag readability by tags being placed too deep, too shallow, or folded. Despite difficulties encountered while trying to administer VIAlpha tags to non-anesthetized juvenile salamanders, we observed no significant differences in tag readability between anesthetized and non-anesthetized individuals ($F_{1,22} = 0.30$, $P = 0.591$). If anesthesia is not preferred, restraining the salamander in a plastic bag and injecting the tag through the side of bag directly into the tail of the salamander is an effective technique with practice. The tradeoff of attempting to insert VIAlpha tags into non-anesthetized individuals is the potential for increased stress from prolonged handling time (however, no one has yet measured the level stress induced by exposure to MS-222 solution).

The mean readability score for Marbled Salamander juveniles after four weeks was 3.33 ± 0.16 (± SE; N = 24), indicating that a typical alphanumeric code could be read clearly by employing both the blue LED light and amber filter glasses. Marbled Salamanders are particularly darkly pigmented compared to other ambystomatids and we would expect their readability scores to be lower than more lightly pigmented species. For example, the comparably paler Spotted Salamander juveniles we monitored for twelve weeks had a mean readability score of 3.91 ± 0.03 (N = 103). A typical Spotted Salamander alphanumeric code could be clearly read without amber filter glasses. To ensure optimal readability, tags should be positioned just below translucent epidermis and inserted far enough away from the entry wound to allow it to heal and to prevent scar tissue from obscuring the alphanumeric code. Although we found that shining a blue LED or UV light and wearing amber filter glasses provided by NMT greatly improved tag detection in more heavily pigmented salamanders, for individuals with little

translucent skin or abundant patterning, VIAlpha tags may not be a viable marking technique.

Tag reading accuracy is a potential problem when reading 1 mm alphanumeric codes. Our observer incorrectly read 4% of 227 total tag reading attempts and 10% of 30 VIAlpha tags were misread at least once. Our results are similar to those of Heard et al. (2008) who reported a VIAlpha tag misidentification rate by naïve observers in 3% of attempts. By comparison, Bailey (2004) reported a lower reading accuracy of 13% for VIEs due difficulty finding marks or color misidentifications. PIT tags probably have the lowest rate of inaccurate readings, although Pyke (2005) attributed a 1.8% error rate to human recording error.

Placement of tags too close to the entry wound was the primary cause for tags being dropped. For the first two weeks we recorded 100% tag retention, but by the end of week four 20% of 30 tags were dropped. Though not significant ($P = 0.218$), all six dropped tags were from non-anesthetized salamanders and could be the result of less than optimal tag placement while attempting to restrain them by hand. We found similar results in tag retention over twelve weeks for anesthetized Spotted Salamander juveniles (16% of 122 were dropped), suggesting that the problem of tag retention may be independent from the use of anesthesia. Tag loss may be the greatest potential limitation of VIAlpha tags. Heard et al. (2008) observed rates of tag loss of ~8% in frogs, which they attributed to expulsion of tags from slow-healing entry wounds. Tag loss has also been reported in PIT tags (Gibbons and Andrews 2004) however it has not been observed for VIEs (Bailey 2004; Moosman and Moosman 2006; Nauwelaerts et al. 2000) except when individuals are marked prior to metamorphosis (Grant 2008). Heard et al. (2008) suggest mark duplication as possible insurance against tag loss. Adding a cohort toe clip or a VIE mark in conjunction with a VIAlpha tag could be helpful, however at a potential cost in handing time and stress. During the twelve weeks we made observations, a small scar was almost always detectable upon close inspection, allowing us to identify individuals with lost tags in the field.

For individually identifying large numbers of small juvenile salamanders, VIAlpha tags are a reliable and effective marking system. They have both advantages and disadvantages when compared to VIE marks and PIT tags. While PIT tags are very effective for individual identification of larger individuals, they are not yet available in small enough sizes to be practical for most recently-metamorphosed salamanders and require a more invasive surgical procedure. VIAlpha tags and VIE marks are both effective marking systems for small amphibians and each has trade-offs. One key advantage of using VIAlpha tags in salamanders, however, is that they do not appear prone to migrate to other regions of the body as reported with VIE marks. While VIEs do not appear to be as prone to tag loss as VIAlpha tags (8–20%), the reported misidentification rates for VIEs (13–31%) appear to neutralize this advantage. According to the estimation of Nauwelaerts et al. (2000), VIEs cost about $0.06 per mark which is much less expensive than ~$1.00 per VIAlpha tag or ~$6.00 per PIT tag. The price advantages of VIEs may be somewhat diminished when multiple colors and locations are used to create individual marks, plus a proportion of a VIE batch is often wasted due to premature hardening in the field. Ralston Marold (2001) reported material costs for her project increased substantially because of the need to mix multiple batches per day despite keeping VIEs on ice. VIAlpha tags are very practical for fieldwork because they are extremely compact, lightweight, and are as visible as VIEs without requiring refrigeration.

Ultimately, which marking technique is the most appropriate depends on the question being asked. Here, we were concerned with individual identification of thousands of small, recently metamorphosed salamanders. Our field experiments required identification of recaptures over relatively short time periods (1–12 weeks). For our short-term projects, VIAlpha tags worked well, however long-term retention and readability has yet to be tested and is of concern. Marking juvenile salamanders with any method can be problematic because of their high rate of growth and development of pigmentation and patterning. We recaptured several Ringed Salamander juveniles the following field season with their tag color still discernable but their alphanumeric code mostly obscured. Although often tedious and slow when first used, an experienced operator can load and accurately inject tags swiftly with progressively decreasing handling time. When compared to other available marking techniques, the speed of use, cost, detection and readability, number of individual combinations, and lack of observed negative effects on survival or behavior, suggests that VIAlpha tags are highly effective for individual identification of small juvenile salamanders.

Acknowledgments.—All procedures were approved by the University of Missouri Animal Care and Use Committee (protocol #3368). All salamanders were collected with a Missouri Wildlife Collecting Permit. This research was supported by NSF Grant DEB 0239943 to RDS. We thank J. Geib for helpful comments on an early draft. M. Mahoney and an anonymous reviewer provided excellent suggestions for the final manuscript.

Efficacy of Small Diameter Pipe-trap Refugia for Capturing Metamorph Treefrogs

DANIEL J. LEACH
Division of Biological Sciences, University of Missouri
Columbia, Missouri 65211, USA
e-mail: djl8r4@gmail.com

Pipe-trap refugia are currently the most widely used method for sampling hylid frogs in their terrestrial habitats (Johnson et al. 2008; Myers et al. 2007; Pittman et al. 2008). Several studies have validated the technique for a variety of species and highlighted the potential for modifications of pipe-traps targeting specific species or age classes (Bartareau 2004; Moulton et al. 1996; Zacharow et al. 2003). In a study of Gray Treefrog (*Hyla versicolor*) habitat use in mature oak-hickory forest within Daniel Boone Conservation Area, Warren County, central Missouri,

I tested a scaled-down variant of the artificial pipe-trap refugia design used by Johnson (2005). I modified the pipe-trap in an attempt to enhance capture rates of metamorph Gray Treefrogs, a crucial life stage for which the ecology remains poorly understood. Metamorph-specific pipe refugia were constructed in the same manner as the larger pipe-traps after Johnson (2005), but with a gray 18 mm (pipe interior diameter) polyvinyl chloride (PVC) pipe rather than the black 40 mm acrylonitrile butadiene styrene (ABS) pipe used for the larger pipe-traps. The reduced pipe diameter maintains accessibility for metamorph treefrogs while effectively excluding adult treefrogs. The restricted pipe diameter also limits access for several other bycatch species that may influence treefrog occupancy (e.g. skinks, spiders, katydids; pers. obs.) and reduces risks of mortality for bycatch species who are themselves in danger of entrapment (e.g. skinks, pers. obs.; flying squirrels, Borg et al. 2004). Finally, the pipe diameter excludes potential predators that have been found in larger pipe-traps such as the Black Rat Snake (*Elaphe obsoleta*, pers. obs.).

I distributed 96 large and 96 small pipe-traps evenly throughout three experimentally treated forest plots surrounding permanent forest ponds. Each of the three sites was comprised of four treatment areas: 4–5 year old clearcuts (with one treatment area having coarse woody debris from logging retained and one treatment area with coarse woody debris reduced), partially-thinned forest stands, and unmodified control forests (32 pairs of pipes at each site, 24 pairs of pipes in each habitat type). Pipes were placed on a wide variety of trees representative of the range of species occurring in the area, including White Oak (*Quercus alba*), Black Oak (*Q. velutina*), Red Oak (*Q. rubra*), Shagbark Hickory (*Carya ovata*), Flowering Dogwood (*Cornus florida*), Black Cherry (*Prunus serotina*), and Black Maple (*Acer nigrum*). Pipe-traps were placed in pairs on trees with the open upper end of the pipes approximately two meters above the ground. Within pairs, one large and one small pipe were placed side-by-side on a single tree to allow direct comparison of the effectiveness of the smaller refugia for sampling metamorphs. In clearcuts where some trees were too small to place both pipes on a single tree, pipes were placed on trees of the same species and approximate diameter within 5 meters of one another.

I monitored all pipe-traps 3 times weekly over two seasons of monitoring from May through October in 2007 and 2008, and assigned each individual a unique mark using toe clips. I recorded 55 captures of 32 individual Gray Treefrog metamorphs in pipe-traps. Comparison of metamorph captures between large and small pipe-traps showed gross capture rates of 83% (46 captures) in large pipes and 17% (9 captures) in small pipes. Of the 32 individuals captured, 4 were recaptured in adjacent pipes of different diameters showing repeated use of adjacent refuges of both sizes. Spring Peepers (*Pseudacris crucifer*), the only other hylid species occurring in the study area, were only rarely found occupying the larger pipe-traps and were never found in the small diameter traps. While adult treefrogs, large spiders, skinks, and katydids would occupy the large pipes, only metamorph treefrogs were found occupying the small diameter pipes. However, spiders would frequently deposit an egg sac near the mouth of the pipe temporarily obstructing access and potentially precluding occupancy by metamorph treefrogs.

Previous studies comparing the effects of different pipe diameters on capture rates of hylid frogs have shown differential capture rates among multiple species as well as among age-classes within species. Bartareau (2004), in a study of ground-placed pipe-traps of three different diameters (13, 25, and 38 mm), reported a significant positive relationship between pipe diameter and treefrog size across species. The design that I tested for a reduced diameter (18 mm as compared to 40 mm) tree-based pipe-trap targeting Gray Teefrog metamorphs was partially unsuccessful in that it did not show improved capture rates of metamorph Gray Treefrogs compared to traps of a larger pipe diameter. However, the small diameter pipe did effectively exclude adult treefrogs and the bycatch species commonly found in the large pipe-traps. Further testing of pipe-traps of intermediate diameters will help determine the suitability of such modifications for targeting Gray Treefrogs of different age classes. Pipe-traps remain one of the best techniques currently available for studying Gray Treefrogs and many other hylids in their terrestrial environments. I strongly encourage further testing of new pipe-trap designs utilizing intermediate pipe diameters or other modifications to further refine the technique and its applications. Such modifications could lead to the development of age-class or species-specific pipe-traps for hylid frogs, ultimately facilitating studies that examine the ecology and conservation of these species.

Venom Canal Occlusion as an Experimental Alternative to Surgically-rendered Venomoid Snakes in the Copperhead, *Agkistrodon contortrix*

In a study of the time of passage of prey through the digestive tract of a Copperhead (*Agkistrodon contortrix*) to compare the efficiency of digestion between envenomated and non-envenomated prey, it was planned to employ an intact snake as its own control and then surgically remove its venom glands and use it as an experimental subject. Much of the literature about this topic is found in relatively obscure sources (Alpi et al. 2009). Although Tait (1938) established a procedure for excising the venom gland of pit vipers, later refined by Langlada and Belluomini (1972), it is invasive and can result in formation of hematomas and other complications. With that technique, healing requires an extended convalescence but is not always complete. An alternate technique developed in an effort to establish a less drastic method is the occlusion of venom ducts using electrocautery (Jaros 1940). This technique has been reported to be superior to extirpation of the venom gland, but would require highly specialized microsurgical techniques to achieve a theoretically possible reversal of the ablation. This technique also requires an extended convalescence and healing is not always complete. The present study attempted to create an easily reversible alternative to these invasive techniques by testing whether dental composites would effectively block flow of venom through the fangs of the Copperhead.

Table 1. Shedding of fangs by Copperheads (*Agkistrodon contortrix*) following occlusion.

Dental Composite	Snake No.	Successfully Occluded	Time to Shedding (post-treatment)
Visible-light-cured glass ionomer restorative	12 (first attempt)	Yes	Before day 6
	12 (second attempt)	Yes	Before day 15
	7	Yes	Before day 15
Light-cured, radiopaque, flowable composite	3	Yes*	Before day 24
	4	Yes	Before day 10
	9	Yes	Before Day 6
	10	Yes *	Before day 6

* The dentist indicated at the time of the procedure that he was not confident he had completely occluded these two fangs. When an attempt was made subsequently to milk the snake there was minor leakage that was barely perceptible.

Methods.—Prior to the surgical studies, fangs of Copperheads dissected from deceased specimens were examined by scanning electron microscopy to ascertain the general characteristics of the interior surface of the fang and to assess the potential for direct filling without amputation of the tooth. The structure of the fang's opening was considered incompatible with a pressurized fill technique and the smooth featureless surface of the fang's interior suggested that a glass ionomer fill might have the best chance of full adherence using a pressurized fill on a partially coronectomized tooth.

Six Copperheads were housed at North Carolina State University's A.E. Finley Research and Education Center located at Historic Yates Mill County Park near Raleigh, North Carolina. Snakes were subjected to treatment on separate days. Prior to treatment each snake was milked and the venom collected into a 150-ml glass beaker covered by Parafilm. Then, the snake was placed into an individual reinforced rubberized container and transported by automobile to the North Carolina State University

College of Veterinary Medicine where it was placed into a clear Perspex tube appropriate to its girth and anesthetized.

Following induction with 5% isofluorane, the snake was intubated with an appropriately sized endotracheal tube and dosage was adjusted according to the snake's physiologic parameters and plane of anesthesia. Heart and respiratory rates were monitored every five minutes for each snake; the snake was then carefully observed for muscle tone and any voluntary movement during treatment. The crown of each fang was amputated approximately halfway down its length using a tapered diamond burr on a high-speed handpiece with water cooling and the fang filled with a dental restorative (Fig. 1). A visible-light-cured glass ionomer (GC Fuji II LC distributed by GC Corporation, Tokyo, Japan) was used for snakes #12 and #7. A radiopaque, flowable composite (PermaFlo Purple distributed by Ultradent Products, Inc, Utah, USA) was employed for the remaining four.

Following the procedure the snakes were returned to the housing facility at Yates Mill Park and monitored daily for any aberrations in behavior. The fangs of the treated snakes were visually examined six to eight days post-operatively to ascertain whether or not they were intact. An attempt was also made to milk the snake to discover whether occlusion of the fang had been successful. If the fangs were not shed by eight days, they were checked intermittently thereafter.

Results and Discussion.—Table 1 demonstrates that both composites successfully occluded the snakes' fangs but because snakes shed their fangs within a short time post-treatment, sometimes within six days, the occlusion was not long-lasting. The times in Table 1 indicate when the new fang was first observed, but in some cases replacement could have occurred earlier.

It is not clear whether the occlusion of the venom canal induced exfoliation or whether fang shedding naturally occurs at this interval. A study is now in progress to ascertain the normal rate of fang replacement.

Once the natural rate of shedding is known, experiments of short duration could be planned to begin at the inception of the new shedding cycle. Occlusion of the venom canal in the fang, however, does not seem a viable alternative for long-term experiments. Following the use of the dental composites, shedding of the occluded fangs took place with the replacement fang being operative.

Although the procedure is unsuccessful for long-term experiments, it is a valid technique for the blockage of venom over short periods. There were only two instances in which the technique was not completely successful in blocking the flow of venom, causing slight leakage to occur. In both these cases immediately after the procedure the surgeon indicated he had experienced difficulty and was not positive he had blocked the fang completely.

Acknowledgments.—This research was carried out with approval by the North Carolina State University Institutional Animal Care and Use Committee under protocol 08-151-O

Using Livestock Markers to Individually Identify Communally-housed Chuckwallas (*Sauromalus ater*) at the Bronx Zoo

The ability to individually identify animals is important in many types of biological studies. Mark-recapture studies are often utilized in the investigation of numerous natural history parameters of wild populations of animals including lifespan, habitat use, home range and behavior. Individual recognition is important to *ex-situ* managed populations as well. In zoos, accurate animal identification is essential to animal health, record keeping, breeding programs and collection management. This information is vital for the implementation and coordination of the Association of Zoos and Aquariums Species Survival Plans.

Various techniques have been developed and employed for individual recognition in reptiles (see Ferner 2007). The most appropriate should be minimally invasive, allow for easy recognition (ideally from a distance), and persist or be easily maintained. Both scale- and toe-clipping (Waichman 1992; Woodbury 1956) have been performed in the field and on captive animals, but both require the handling of individual animals for subsequent identifications. Scale-clipping can be unreliable as scales might re-grow. Toe-clipping can negatively impact locomotion (Bloch and Irschick 2004) and might affect survivorship as has been suggested by some amphibian studies (Clarke 1972; McCarthy and Parris 2004). Branding has been described (Clark 1971), but also requires handling of the animal for recognition. The attachment of colored beads to lizard species using various techniques has been reported. Because beads are not shed, this technique could be effective long-term. However, the invasive methods utilized by Fisher and Muth (1989) and Rodda et al. (1988) are not appropriate in a zoo setting as they might prove distasteful to the public. All of these techniques probably involve some discomfort to the animal as well as possible infection at the site. Implantation of passive integrative transponders (PIT tags) is one of the most commonly employed recognition techniques utilized for all taxonomic groups (Gibbons and Andrews 2004) and has the benefit of potentially persisting throughout the life of the animal. Unfortunately, animals must reach a certain size before PIT tags become practical. And although PIT tags offer a reliable source of identification, individual recognition still requires some handling of the animal. Painting has been employed on various squamates (Brown et al. 1984; Jones and Ferguson 1980; Rodda et al. 1988; Simon and Bissinger 1983; Vinegar 1975). This technique might make individuals more visible and vulnerable to potential predators, although Jones and Ferguson (1980) and Simon and Bissinger (1983) reported no effect on survivorship in *Sceloporus undulatus* and *S. jarrovii*, respectively. Further study is needed to determine effect of painting on survivorship and social significance (Ferner 2007), the latter of which could affect adult zoo animals while predation pressure does not. In hopes of safely and effectively identifying Common Chuckwalla (*Sauromalus ater*) hatchlings at the Bronx Zoo without handling, we employed painting tail bands using livestock markers.

Nine Common Chuckwallas hatched between 24 September and 26 September 2010 at a mean (± 1 Standard Error) mass of 5.27g (± 0.141). All hatched with the expected alternating black and white banded tails. On 30 September, linseed oil-based All-Weather Paintstick® livestock markers (LA-CO®, Elk Grove, Illinois, USA) in red, blue or green colors were used to mark them. The distinct white bands were numbered in ascending order from the cloaca to the tail tip. A strip of color was applied to one of these three bands in each animal, in one of the three colors. Animals were then referred to by color and band number (e.g., Red-1 referred to the animal marked red on the first white band). The livestock marker was applied using a fine tipped file and gently applied to the skin. Although several tools could be used for marking, the texture of the file allowed the livestock marker to adhere easily to its surface during application. Excess marker was removed with the edge of the file. Animals displayed no signs of discomfort and behavior was not obviously altered by the markers. All the marks remained easily

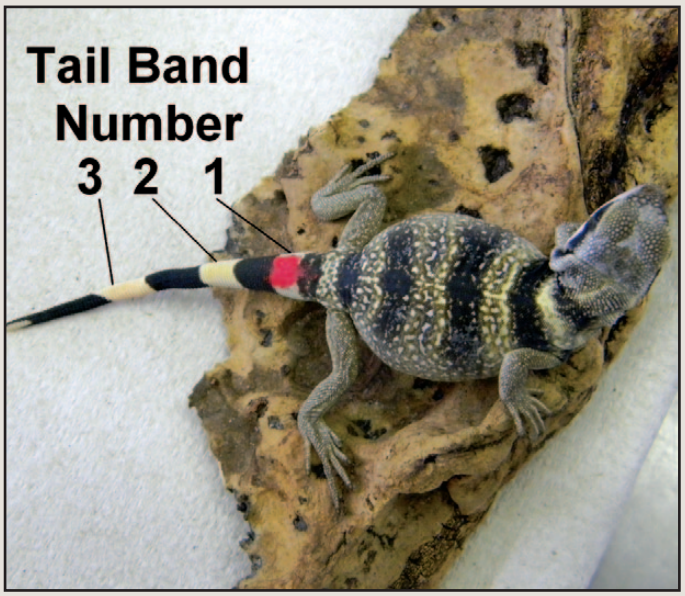

FIG. 1. Tail band numbers of a hatchling Common Chuckwalla (*Sauromalus ater*) Red-1 (i.e., marked with red Paintstik on the anterior-most white tail band [tail band #1]).

distinguishable when they were proactively touched up on 22 October. The red and green colors were the easiest to discern; the blue marker attracted or held substrate more readily making the mark appear a dull brown color, a disparity likely due to a slight difference in ingredients used to manufacture the color (Bachleda, LA-CO, pers. comm.). When the blue mark was wiped free of debris, however, the color was obvious. Because the red and green marks were so vibrant, the blue marks were still easily distinguishable from the other two colors. No marks disappeared until animals began shedding on 20 November at which point colors were reapplied as each animal shed.

Some of the benefits of this technique were realized immediately. The marks took little time to apply and required only minimal maintenance. Animals could be individually identified to monitor behavior (e.g., food consumption) with negligible or no disturbance to them. The markers are ideal for use with communally-housed animals in captive situations where some of the more invasive techniques would stress the animals and potentially alter behaviors. It is a viable, noninvasive alternative to marking animals too small to receive PIT tags. Paintstik markings could also be useful in short-term field studies, allowing individuals to be distinguished from a distance so that an observer would not alter the animals' behavior. Location of marks on the body can be easily adapted to each species.

Paintstiks are readily available, inexpensive (costing around US $1.00 each), and come in nine colors, with an additional four colors available in fluorescent, allowing for a significant number of possible combinations. With each stick useful for hundreds of applications, this technique is optimal for short-term use where PIT tagging is cost prohibitive. Additionally, it is much less invasive than PIT tagging, and animals can be identified from a distance. With longer intervals between sheds, adult animals might display Paintstik marks for much longer than the juveniles discussed here. Similarly, body location might affect longevity of the mark with Brown et al. (1984) reporting acrylic paint marks lasting four years when applied to the basal segments of the rattles of *Crotalus viridis*.

Acknowledgments.—We thank the Bronx Zoo Herpetology Staff for their assistance, particularly Brandon Casey and Alyssa Borek. We are also grateful to Pat Thomas and Valorie Titus for reviewing an earlier version of this manuscript.

AMPHIBIAN DISEASES

This section offers a timely outlet for streamlined presentation of research exploring the geographic distribution, host range, and impact of emerging amphibian pathogens, especially the amphibian chytrid fungus *Batrachochytrium dendrobatidis* (*Bd*) and ranaviruses. *Bd* is an emerging pathogen linked to mass mortality and declines of amphibians worldwide, yet *Bd* has also been detected in amphibians without disease. Ranaviruses also cause mass mortality, but have not yet been linked to large-scale declines. We know relatively little about their global distribution, host range, or impacts on host populations. To improve our understanding of the scope of this issue, we encourage submission of studies that illuminate the geographic distribution, host ranges, and impact of these pathogens on amphibian populations, including research on individual species or groups of species, wild or captive animals, native or non-native species, live animals or museum specimens, environmental samples, and, provided there is sufficient sampling[1], reports of non-detections.

We ask authors to: 1) restrict the Introduction of their paper to a maximum of two paragraphs to highlight the context of their study; 2) briefly include both field and laboratory Methods; 3) present Results in a Table, although a map might also be useful, and limited text; and 4) have a short discussion of a maximum of three paragraphs to touch upon key findings. Please include the following information in submissions as appropriate: coordinates and description of sampling areas (or please note if locations are extremely sensitive to reveal, and provide general area instead); species name(s) and life history stages examined, as well as other species present; whether samples were collected randomly or just from dead or moribund animals; date of specimen collection; evidence of unusual mortality; numbers of positive and negative samples; disposition of voucher specimens; name of collaborative laboratory or researcher conducting histological sections or PCR analyses; and names of cooperative land owners or land management agencies. We encourage researchers to conduct post-mortem examinations when possible to identify the cause of death when reporting mortalities. We aim to expedite the review and publication process! Please e-mail submissions directly to Associate Editor, Dr. Dede Olson: dedeolson@fs.fed.us.

[1]If a sample of 30 individuals of a particular life history stage of a particular species yields no positive results, and the diagnostic test is highly sensitive, one can conclude that the prevalence of infection is less than 10% with 95% confidence. With a sample of 10 an infection in one of four individuals could go undetected. We encourage researchers to collect sufficient samples that negative results are meaningful.

Dynamics of Chytridiomycosis in a Tasmanian Frog Community

Most previous studies of the prevalence of chytridiomycosis (*Batrachochytrium dendrobatidis*, *Bd*) in wild frog populations in Australia have been in tropical or subtropical environments, in areas with predominantly summer rainfall (Kriger and Hero 2007; Kriger et al. 2007; McDonald et al. 2005). As Tasmania is both more temperate and does not have a summer-dominated rainfall pattern, seasonal patterns in prevalence in Tasmania may not be the same as in other parts of Australia. In tropical and subtropical areas of Australia, *Bd* prevalence and clinical disease are both higher in the colder and drier winter months (Berger et al. 2004; Kriger and Hero 2006; Retallick et al. 2004). In a broad-scale latitudinal study of chytridiomycosis in the *Litoria lesueuri* complex in eastern Australia, Kriger et al. (2007) found that prevalence and intensity of *Bd* infection increased with latitude, with an order of magnitude increase in the intensity of infection (as measured by zoospore equivalents) from 17° to 37°S. This latitudinal variation appeared to be related to a negative association between infection intensity

and temperature in the warmest quarter of the year and a positive association between infection intensity and rainfall in the driest quarter. They suggested that temperate frog populations might therefore be particularly susceptible to chytridiomycosis, especially as substantial population declines have occurred in at least 11 frog species in south-east Australia (Hero et al. 2006). However, the highest latitude they examined was 37.26°S, close to the Victoria-New South Wales border, which is still in a region of predominantly summer rainfall.

Chytridiomycosis has only recently been reported from Tasmania (Obendorf 2005; Obendorf and Dalton 2006; Pauza and Driessen 2008). It has been detected in samples from a number of sites surrounding the World Heritage Area in south-west Tasmania, in tadpoles of all four frog species surveyed (*Litoria burrowsae, L. ewingii, Crinia signifera*, and *C. tasmaniensis*; Pauza and Driessen 2008). There are concerns that it may threaten Tasmania's three endemic anurans (*Litoria burrowsae, Bryobatrachus nimbus* and *Crinia tasmaniensis*; Pauza and Driessen 2008) and also the threatened green and gold frog, *Litoria raniformis* (Obendorf and Dalton 2006). There has not, however, been any quantitative examination of prevalence or intensity of infection in adult frogs, as distinct from tadpoles, in Tasmania. Our objective in this brief study was to address this gap in knowledge by estimating prevalence and intensity of *Bd* infection, and possible effects of *Bd* infection on survival and capture probability in two Tasmanian frog species.

Our study site was in Knocklofty Reserve, Hobart, Tasmania. The reserve usually has several small ponds with the Brown Tree Frog *Litoria ewingii*, the Spotted Marsh Frog *Limnodynastes tasmaniensis*, and the Common Froglet, *Crinia signifera* (http://www.friendsofknocklofty.org/fauna.html; accessed 5 July 2010). These species are common in Tasmania and also are found in southern mainland Australia (Barker et al. 1995). At the time of the study, southern Tasmania was in severe drought, with 24-month cumulative rainfall to 1 March 2008 in the lowest 5% of historical totals (http://www.bom.gov.au/climate/drought/archive/20080304.shtml; accessed 5 July 2010). Only one water body, a small flooded quarry at 42.881°S, 147.303°E, still held water at the time of the study in Knocklofty Reserve. All data collection was therefore concentrated at that site.

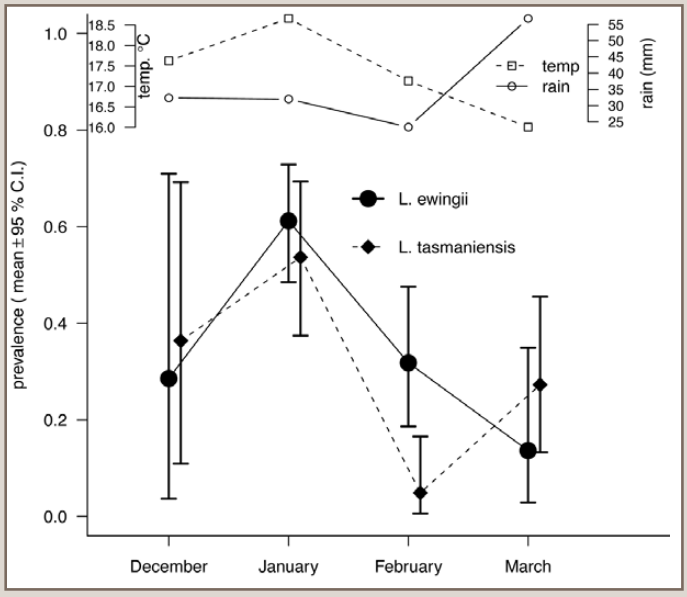

FIG. 1. Prevalence of *Batrachochytrium dendrobatidis* infection in *Litoria ewingii* (solid circles) and *Limnodynastes tasmaniensis* (diamonds) per monthly survey period, December 2007 to March 2008, from Knocklofty Reserve, Tasmania, Australia. Rainfall (circles) and mean temperature (squares) in the 30 days preceding each sampling period are shown.

We conducted fieldwork from December 2007 to March 2008, with monthly field surveys of 4–5 days, conducted in late afternoon and early evening. Frogs were captured by hand after searching under rocks and logs around the edge of the pond. On first capture, adult frogs were measured using calipers and individually marked using toe "tipping." No more than 2 mm of the toe tip was removed and a maximum of one toe tip per foot or 4 toe tips per individual were removed. To minimize spread of disease between individuals, all frogs were placed into individual plastic bags immediately after capture and field gear such as scissors and callipers were disinfected in 70% ethanol between uses on individual frogs. Individual frogs were handled with a new pair of latex disposable gloves. The first time an individual frog was captured during one of the monthly survey periods, it was swabbed for *Bd* detection using a standardized technique as described by Kriger et al. (2006), using individually packed sterile dry swabs (MW100-100, Medical Wire and Equipment Company, Bath, UK). Frogs were swabbed 10 times on their ventral and dorsal surfaces, 10 times on each side from the fore to hind limbs and five times on each foot.

Swabs were processed using real-time quantitative TaqMan PCR (qPCR) as described by Boyle et al. (2004) and Hyatt et al. (2007) with modifications as described by Garland et al. (2009). DNA extracts from swabs were diluted and added to PCR reactions and analyzed in groups of 22 swabs, and in each group, a negative control swab (negative extraction control - NEC) and a positive extraction control swab (PEC) were processed. The TaqMan analyses were performed in triplicate for the sample extracts, NEC, no template controls (NTC) and PEC. Standards (100, 10, 1, 0.1 zoospore equivalents) were analyzed in quadruplicate. Analyses were performed on the Rotor-GeneT 6000 (Corbett Research) using Gene-Disc 100 tubes and a set threshold of 0.01 to determine the PCR cycle at point of detection (Cycle threshold (Ct)). PCR master mix and diluted sample extract, diluted NEC, PEC, water (NTC), or standard, were added to the tubes with a CAS-1200T pipetting robot (Corbett Robotics). NEC, PEC, NTC and standards were analyzed together by qPCR for each group of 22 swabs.

Sample extracts obtaining a negative result for the TaqMan assay were reanalyzed for inhibition by assessing amplification of the TaqMan exogenous internal positive control. Single analyses were performed. If the Ct value of the IPC was above 32 then the extract was diluted to 1 in 100 and a second TaqMan

TABLE 1. Recapture rates and *Batrachochytrium dendrobatidis* (*Bd*) infection status at time of first capture for *Litoria ewingii* and *Limnodynastes tasmanienisis* at Knocklofty Reserve, Tasmania, Australia. Frogs caught in the last of the four sampling periods could not have been recaptured in a subsequent sampling period, hence the percentage of frogs recaptured in the final column is based on frogs captured in the first three sampling periods only. Frogs with uncertain infection status on first capture have been omitted (*L. ewingii*: N = 11; *L. tasmaniensis*: N = 17).

Species	*Bd* infection status at first capture	N	*Bd* prevalence	No. frogs captured in first three sampling periods	No. (%) recaptured in a subsequent sampling period
Litoria ewingii	Negative	77		62	1 (2)
	Positive	56	42%	56	6 (11)
	TOTAL	133		188	7 (6)
Limnodynastes tasmaniensis	Negative	59		50	21 (42)
	Positive	27	31%	23	7 (30)
	TOTAL	88			
Crinia tasmaniensis	Negative	0		0	0
	Positive	1	100%	1	1 (100)

assay (in triplicate) was performed on the inhibited sample. Samples where 1 or 2 only of the triplicate qPCR reactions were positive were regarded as inconclusive and not included in any analyses.

Program MARK (Cooch and White 2010) was used to model capture-mark- recapture data, examining whether *Bd* infection affected frog survival or capture probability. Initially, capture probability models were constructed with fully saturated survival models. Secondly, survival and transition rates were modelled using the best supported capture models from the first step and evaluated using AICc weight. Model selection uncertainty was accounted for by model averaging (Burnham 2002; Burnham and Anderson 2004). Prevalence was analyzed using logistic models implemented in R (R Development Core Team 2007). When the same individual was captured on multiple occasions in the same survey period, it was treated as a single observation and was scored as positive if it was clearly positive (3 of the 3 replicate qPCR reactions) on any of the capture occasions and negative if it was clearly negative (0 of 3 qPCR reactions) on at least one of the capture occasions, even if inconclusive (see above) on some of the others. For analysis of infection intensity (zoospore counts), the maximum count per individual per sampling period was used in the analysis.

At the time of first capture, 42% of *L. ewingii* (N = 133) tested positive for *Bd*, whereas 31% of *L. tasmaniensis* (N = 88) tested positive (Table 1). However, a Fisher's exact test did not reject the null hypothesis of equal prevalence in the two populations (P = 0.09, 95% CI for odds ratio 0.33, 1.11). The one *C. signifera* individual captured was infected with *Bd*.

Overall, *L. tasmaniensis* had a much higher recapture rate (38%) than *L. ewingii* (6%). A logistic model of recapture probability in subsequent sampling intervals as a function of species and infection status at the time of first capture showed that there was a significant interaction term (χ^2 = 5.52, 1 df, P = 0.019). A borderline significantly higher (P = 0.052 ; Fisher's exact test) proportion of infected *L. ewingii* were recaptured (10.7%) as compared to noninfected individuals (1.6%). In *L. tasmaniensis*, there were more recaptures of noninfected individuals (42%) as compared to infected frogs (30%), although a Fisher's exact test did not reject the null hypothesis of equal recapture probability between these species (P = 0.44).

Although the prevalence of infection differed between *L. tasmaniensis* and *L. ewingii* captured in each of the four monthly survey periods (Figure 1; logistic model of prevalence as a function of species and collection month had a significant interaction term; χ^2 = 11.2, 3 df, P = 0.01), inspection of the data suggested that prevalence was similar for both species in December, January, and March, but was significantly lower in *L tasmaniensis* than in *L. ewingii* in February. Whereas the mean temperature in the 30 days preceding the sampling period appeared to be positively associated with prevalence (χ^2 = 29.8, 1 df, P = 0.00001; see Fig. 1), a model including month, species and their interaction fitted the data significantly better than a model including species, temperature and an interaction (χ^2 = 17.3, 4 df, P = 0.002), indicating that temperature was not a sufficient explanation for the observed differences in prevalence between months and species. Similarly, although the interaction between species and the total rainfall in the 30 days preceding the sampling period was associated with prevalence (χ^2 = 4.35, 1 df, P = 0.03), it was not sufficient to explain the observed differences in prevalence (χ^2 = 43.0, 4 df, P ≈ 0).

Capture-Mark-Recapture modelling was only possible for *L. tasmaniensis* because the recapture rate for *L. ewingii* was too low to provide sufficient data. Models with constant capture probability and models with capture probability dependent on infection status were almost equally well supported (AICc weights 0.33 and 0.36, respectively). Models with survival dependent on disease status were more weakly supported (total AICc weight 0.19) than those in which survival was independent of disease status (Total AICc weight 0.44). Model-averaged estimates of *L. tasmanienisis* monthly survival were

therefore almost identical for diseased individuals (0.60, SE = 0.16) and non-diseased individuals (0.59, SE = 0.13), whereas the model-averaged capture probability for diseased individuals was 0.41 (SE = 0.13), in comparison with 0.55 (SE = 0.16) for non-diseased individuals. Models including an effect of temperature on either recapture (Total AICc weight 0.18) or survival (Total AICc weight 0.25) were not well supported.

Geometric mean infection intensity (as measured by zoospore counts) in infected frogs was 24.0. There was no evidence that the monthly variation in this intensity differed between the species ($F = 1.50$, $df = 3, 87$; $P = 0.22$) or that the intensity of infection differed between the species overall ($F = 0.77$, $df = 1, 7$; $P = 0.38$). However, the difference in infection intensity between months was of borderline significance ($F = 2.70$, $df = 3, 87$, $P = 0.051$).

We found evidence that the proportion of infected frogs that were recaptured, relative to the proportion of uninfected frogs that were not recaptured, differed significantly between *L. ewingii* and *L. tasmaniensis*. Several previous studies have used the proportion of frogs recaptured as a proxy for survival but such an effect can be due to differences in survival or catchability. In this case, the difference in recapture rates appeared primarily to be due to higher recapture rates of infected *L. ewingii* compared to uninfected *L. ewingii,* which suggests that there may be behavioral differences between infected and uninfected frogs rather than reduced survival of infected frogs. Whether it is infection status, perhaps by making frogs less active, which increases their probability of recapture, or whether frogs with certain behaviors (perhaps those which are most closely associated with the water body) are more likely to be both infected and recaptured cannot be determined from our results. Overall, the recapture rate of *L. ewingii* was much lower than that of *L. tasmanienisis*. We can only speculate on why this should have been the case, but it is likely to be the result of behavioral differences between the two species.

Using mark-recapture methods, we were unable to detect any effect of *Bd* on the survival of *Limnodynastes tasmaniensis*, despite a relatively high prevalence of *Bd* infection. However, we conducted our study in summer only and there may be mortality due to *Bd* in other seasons. Mortality mainly occurs in winter and spring in northern Australia (Berger et al. 2004; Murray et al. 2009). Akaike weights for models with constant recapture probability and recapture probability depending on disease status were approximately equal and there is insufficient evidence to reject a null hypothesis that catchability is equal between infected and uninfected *L. tasmaniensis*. However, the significant difference between the two species in the effect of infection on recapture probability cautions that infection may influence the probability of capture. Not only does this mean that differences between species in the proportion of frogs recaptured as a function of infection status may not be indicative of differences in mortality induced by the pathogen, but it also means that prevalence in any sample may not be an unbiased estimate of prevalence in the frog population as a whole (Jennelle et al. 2007). This has potential implications beyond our study. With the exception of Retallick et al. (2004) and Murray et al. (2009), neither of which found any indication that infection by *Bd* affected catchability, we know of no other study that has explicitly investigated possible differences in catchability between infected and uninfected frogs. This means that all conclusions drawn about prevalence in populations based on prevalence in samples of adult frogs where catchability of infected frogs has not been assessed need to be treated with caution.

Interestingly, we found that the monthly changes in apparent prevalence differed between our two study species. Although prevalence peaked in both species in January and declined by February, in *L. ewingii* it continued to decline in March, whereas in *L. tasmaniensis* it rose again. This may be a result of behavioral differences between the two species, but it does suggest that the dynamics of infection in these two species, although they were captured around the same water body, are not tightly linked. Little is known about how *Bd* is transmitted in the field. In experimental situations, transmission through water containing zoospores has been demonstrated several times (Berger et al. 1998; Rachowicz and Briggs 2007; Rachowicz and Vredenburg 2004). If this were the predominant means of transmission in the field and species were similar in their contact rate with water, susceptibility to infection and mortality and recovery rates, one might expect that temporal patterns in prevalence would be synchronous in all species sharing the water body in which transmission occurred. Another possibility is that transmission may occur through direct contact between individual frogs, particularly through shared use of shelter sites (Rowley and Alford 2007). If this is the predominant route of infection and there are differences in habitat use between species, then disease dynamics in different species would be less tightly coupled than if transmission occurred predominantly through a shared water body. Our results are consistent with either infection occurring predominantly through a frog-to-frog contact or differences in contact rate with water, susceptibility to infection, mortality and recovery rates.

We detected substantial levels of *Bd* infection in post-metamorphic *L. tasmaniensis.* In a broadscale survey of clinically ill frogs, Berger et al (2004) found six adult *L. tasmaniensis* to have died from chytridiomycosis. Obendorf and Dalton (2006) also reported *Bd* infection in *L. tasmaniensis* but their study investigated only tadpoles. In contrast, Woodhams et al. (2007) attempted to experimentally infect four Australian frog species (*Litoria caerulea, Mixophyes fasciolatus, Litoria chloris* and *L. tasmaniensis*) with *Bd* spores. Only *L. tasmaniensis* failed to become infected and had 100% survival over the course of the experiment. Furthermore, they found evidence that peptide skin secretions of *L. tasmaniensis* inhibited growth of *Bd* in vitro. These conflicting results highlight the importance of using caution when extrapolating laboratory experimental results to the field.

Comparison of infection levels, both in terms of intensity and prevalence, is problematical between sites, species and

seasons, even if a standardized swabbing protocol has been applied in each case. However, it is worth noting that the intensity of infection in our study in both species (approximately 30 zoospore equivalents) was relatively low in comparison with the mean intensity of about 1000 zoospore equivalents reported by Kriger et al (2007) and Kriger and Hero (2006) in *L. wilcoxii* at a similar mean temperature. Pathogenesis of *Bd* is dependent on intensity of infection and may explain the lack of mortality observed in this study (Voyles et al 2009).

Acknowledgments.—This project was funded by an Australian Research Council Discovery Grant (DP0451402) and was carried out under University of Tasmania Animal Ethics Permit A0009732 and a Scientific permit from the Wildlife Management Branch, Department of Primary Industries and Water, Tasmania. We are indebted to David Obendorf for assisting with site selection and frog identification, to Shelly Lachish for assisting with the MARK analysis, Stephen Garland for conducting the PCR analysis at James Cook University and Danait Belay, Sophie Karpiniec, Josiane Eve, Nabil Taff and Jiaxin Li for assisting with the fieldwork.

A Preliminary Survey of *Batrachochytrium dendrobatidis* Exposure in Hellbenders from a Stream in Georgia, USA

Hellbenders (*Cryptobranchus alleganiensis*) are among the largest salamanders in the world. Hellbenders are thought to live over 25 years (Wheeler et al. 2003) and successful breeding populations are generally limited to relatively pristine stream systems. Hellbender populations appear to be declining due to a number of reasons, with habitat degradation such as siltation being a major factor (Briggler et al. 2007a). However, few studies have looked at pathogens as a potential cause of decline.

Batrachochytrium dendrobatidis (*Bd*) has been in the forefront of amphibian disease research in recent years (Duffus 2009). New reports of *Bd* range expansion and host diversity are now common in the literature (e.g., papers in *Herpetological Review*), but studies on the effect of *Bd* on salamander populations is limited, largely because of a lack of knowledge on the status of the populations prior to the introduction of *Bd*. In particular, there is a paucity of information regarding *Bd* in Georgia, USA (Rothermel et al. 2008; Timpe 2008), and few reports of *Bd* in Hellbenders are available: in Missouri and Arkansas, USA (Briggler et al. 2008); in Kentucky, USA (G. Lipps: data available at: www.spatialepidemiology.net/*Bd*-maps). The goal of our study was to obtain baseline data on *Bd* occurrence in a Hellbender population in Georgia.

Hellbenders were collected from Cooper Creek, Union County, Georgia, using a dip-net placed downstream of flipped rocks, as part of another study. Cooper Creek is a fairly swift, medium-sized, rocky-bottomed stream nestled within the Blue Ridge Mountains. Samples were collected opportunistically in March 2009, and in May 2009, additional samples were collected from a site upstream of the March samples. Each salamander was systematically swabbed 20 times along the ventral skin surface and feet with a sterile cotton swab. Samples were stored in individual cryovials, and frozen at -80° C until testing. Genomic DNA was extracted from each swab using the Qiagen DNA Purification Kit (Germantown, MD, USA) following the manufacturer's protocol and each sample was tested in duplicate for *Bd* by polymerase chain reaction (PCR) testing as described (Annis et al. 2004). A sample was only considered positive if both independent PCR reactions were positive; a single *Bd*-positive result was interpreted as being equivocal.

TABLE 1. *Batrachochytrium dendrobatidis* (*Bd*) occurrence in Hellbenders (*Cryptobranchus alleganiensis*) from Georgia, USA.

Age Class	N	No. *Bd*-positive (%)	No. *Bd*-negative (%)	No. equivocal (%)
March 2009				
Adults	17	9	3	5
Juveniles	4	0	3	1
Total	21	9 (43)	6 (28)	6 (28)
May 2009				
Adults	1	0	1	0
Juveniles	5	0	5	0
Total	6	0 (0)	6 (100)	0 (0)
Overall Total	27	9 (33)	12 (44)	6 (22)

In total, 21 of 27 samples had unequivocal results, and 10 of 21 (48%) samples were *Bd*-positive (Table 1). More salamanders were *Bd*-positive during the March sampling period compared with May (Fisher's exact test, $p = 0.0152$); however, the low number of salamanders in the later sample ($N = 6$) may have been insufficient for determining an accurate *Bd* prevalence at that time. Skerratt et al. (2008) recommended sample sizes > 59 when *Bd* prevalence is expected to be low. During the March sampling period, more adults were positive compared with juveniles (Fisher's exact test, $p = 0.0357$), but again low sample sizes may have affected results (Table 1). Unfortunately, due to a freezer failure, the integrity of the 6 equivocal samples was compromised and they could not be retested.

Despite the small sample size of this study, we documented a high prevalence (48%) of *Bd*-positive Hellbenders. To our knowledge this is the first report of *Bd* in Hellbenders from Georgia, although *Bd* has been documented in captive Hellbenders (Briggler et al. 2007b) and in wild Hellbenders from five rivers in Missouri and Arkansas (Briggler et al. 2008), and in wild Hellbenders in Kentucky (G. Lipps, www.spatialepidemiology.net/Bd-maps). Further investigation is needed to determine the effects of *Bd* infection in Hellbenders. However, none of the salamanders that were sampled in our study exhibited clinical signs or had gross lesions suggestive of chytridiomycosis.

It is interesting to note that the samples obtained in March were collected in an area of the stream that is utilized heavily by humans for camping, fishing, and other recreational pursuits. In contrast, the May samples, which were all negative,

were from a relatively isolated site upstream. Additional studies along a gradient in the creek are needed to determine if the difference in *Bd* prevalence may be related to anthropogenic factors. Some species of ranids are common hosts for *Bd* and can serve as reservoirs (Sánchez et al. 2008; Daszak et al. 2004), so differences in amphibian communities between sites may affect prevalence. Additionally, there may be seasonal variation in the detection of *Bd* (Rothermel et al. 2008).

Recent studies on the morbidity and mortality of amphibians due to emerging infectious diseases, such as chytridiomycosis and *Ranavirus*, has highlighted the need to conduct surveillance for these pathogens in an effort to determine possible population effects (Duffus 2009). Although reports of these diseases in various species of salamanders are limited, they are increasing in number and geographic scope. The samples utilized for our study were collected by researchers who were conducting non-disease related research on these salamanders. We encourage others to take advantage of opportunities to collaborate with other researchers in order to carry out pathogen surveillance, particularly in at-risk or cryptic species.

Acknowledgments.—We thank Rod Williams, Shem Unger, and other faculty and students from Purdue University for collecting most of the swabs from Hellbenders in March. Support was provided by the Federal Aid to Wildlife Restoration Act (50 Stat. 917) and through sponsorship from fish and wildlife agencies in Alabama, Arkansas, Florida, Georgia, Kansas, Kentucky, Louisiana, Maryland, Mississippi, Missouri, North Carolina, Oklahoma, Puerto Rico, South Carolina, Tennessee, Virginia, and West Virginia.

Chytrid Fungus Not Found in Preliminary Survey of Lowland Amphibian Populations Across Northwestern Borneo

The emerging pathogen *Batrachochytrium dendrobatidis* (*Bd*) has been implicated in amphibian declines in temperate (Rachowicz et al. 2006) and tropical regions (Lips et al. 2006), but sampling for the fungus has been heavily focused on regions such as North America, Australia, and Europe. Southeast Asia has been comparatively underrepresented in sampling efforts, although *Bd* has been found in the region (Kusrini et

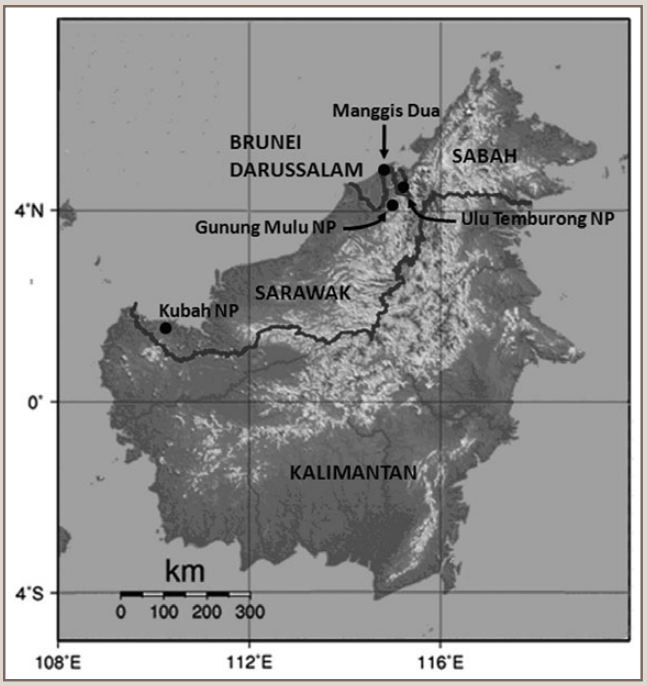

FIG. 1. Sites on the island of Borneo where amphibians were sampled for *Batrachochytrium dendrobatidis*. Gunung Mulu and Kubah National Parks (NP) are located within the state of Sarawak, Malaysia. Ulu Temburong National Park and Manggis Dua are located within Brunei Darussalam.

al. 2008; Neang and Eastoe 2010). The island of Borneo, home to more than 160 amphibian species of which two thirds are endemic (Inger and Stuebing 2005), has remained untested for *Bd*. We tested for *Bd* in northwestern Borneo both in the Malaysian state of Sarawak and in Brunei Darussalam across a variety of habitat types to determine if *Bd* is currently present in the region.

We sampled 16 species of frogs from five different families (Table 1). Animals were sampled opportunistically at five sites across Sarawak, Malaysia and Brunei Darussalam from July through November 2009 (Fig. 1). Sites included urban habitat, national park buffer zone, and core national park areas. All frogs were inhabitants of lowland mixed dipterocarp rainforests except for two individuals sampled from a lowland urban ditch.

Only adults were sampled. Frogs were captured by hand. Skin swabs were taken from pelvic patch, legs, and toes using sterile swabs and stored in 70% ethanol. Clean gloves were used for each individual. Swabs were stored at 20–25°C for 2–4 months and shipped to the United States where they were frozen until extraction. DNA was extracted using a Qiagen QIAamp DNA Minikit. The standard extraction protocol was used. Sample DNA was analyzed using a high resolution melt (HRM) rt-PCR protocol (Boyle et al. 2004; Hyatt et al. 2007) to test for the presence of *Bd* on swabs. Rt-PCR has been shown to be the most sensitive detection method for *Bd* (Boyle et al. 2004; Hyatt et al. 2007). Positive and negative controls were run on the same plate. Samples were run in triplicate.

TABLE 1. Amphibian species and locations sampled for *Batrachochytrium dendrobatidis* in Borneo. Numbers in parentheses indicate total individuals of that species surveyed at that GPS point.

Location	Species	Family
Sarawak, Malaysia		
Gunung Mulu National Park	*Ansonia longidigita*	Bufonidae
	Staurois guttatus	Ranidae
Kubah National Park	*Limnonectes kuhlii* (2)	Dicroglossidae
	Limnonectes paramacrodon	Dicroglossidae
Brunei Darussalam		
Manggis Dua	*Duttaphrynus melanostictus* (2)	Bufonidae
Ulu Temburong National Park buffer zone	*Bufo divergens*	Bufonidae
	Hylarana glandulosa	Ranidae
	Hylarana megalonesa	Ranidae
	Hylarana signata (2)	Ranidae
	Leptolalax gracilis	Megophryidae
	Limnonectes leporinus	Dicroglossidae
	Megophrys nasuta	Megophryidae
	Phrynoidis juxtaspera	Bufonidae
	Rhacophorus pardalis	Rhacophoridae
	Staurois guttatus (2)	Ranidae
Ulu Temburong National Park core	*Ansonia albomaculata*	Bufonidae
	Ansonia longidigita	Bufonidae
	Limnonectes kuhlii	Dicroglossidae
	Meristogenys poecilus	Ranidae

We collected swabs from 23 individuals, and no swabs tested positive for *Bd*. No swab tested positive in triplicate. Furthermore, no single well tested positive, indicating not even weak infection.

We found no evidence of *Bd* in lowland Sarawak, Malaysia or in Brunei Darussalam in this preliminary survey. Our results could be indicative of a small sample size (e.g., Skerratt et al. 2008); *Bd* may currently be present in northwestern Borneo, but we simply failed to detect it. It is also possible that the pathogen has not yet reached the region. Despite substantial fieldwork, we have never observed animals showing symptoms of *Bd*, even at higher elevation sites. *Bd* is thought to grow fastest and be most infectious at lower temperatures (Berger et al. 2004; Piotrowski et al. 2004). The lowland tropical sites we sampled are thus not the ideal habitat for *Bd*, although the fungus does survive in other lowland tropical sites (e.g., Whitfield et al. 2007); *Bd* may however be present or more prevalent at cooler upland sites within this region. We hope to collect samples from these regions in the future for further diagnosis of *Bd*.

We submit that monitoring should continue, however, because if *Bd* is present but was not detected, or if it is introduced in the future, these lowland populations may act as a reservoir (Carnaval et al. 2006; Puschendorf et al. 2006), allowing *Bd* to spread across the island, through amphibians or through humans as tourists or researchers inadvertently carrying *Bd* on boots or on cars. Moreover, several of these lowland species also can be found at higher elevations. For example, Das (2006) found several of the species sampled here within the Crocker Range National Park in Sabah, Malaysia; such wide-ranging species have the potential to carry *Bd* into pristine highland sites where temperature and humidity regimes are more likely to foster chytridiomycosis (Bickford et al. 2010). A *Bd* outbreak could decimate the amphibian fauna of the region, including many poorly-known species and many species of conservation concern. We therefore recommend continued monitoring of the amphibians of Borneo for the presence of *Bd*, with larger samples and inclusion of samples from elevations which would be likely to be conducive to *Bd* outbreaks.

Acknowledgments.—We thank Matthias Dahmen for help in specimen collection as well as John Pollinger and Erin Toffelmier for assistance with PCR. Tom Smith allowed access to equipment for PCR. Cindy Carey and Allan Pessier provided positive control samples. Dede Olson and Jodi Rowley gave helpful comments on an earlier version of the manuscript. We thank the Sarawak Forestry Department and the Universiti Brunei Darussalam for work permission and for issuing export permits.

Detection of *Batrachochytrium dendrobatidis* in Anurans of Cape Cod National Seashore, Barnstable County, Massachusetts, USA

Evidence indicates that the pathogenic fungus *Batrachochytrium dendrobatidis* (*Bd;* Phylum Chytridiomycota; Longcore et al. 1999) has contributed to global declines of amphibian populations (Young et al. 2007) and may be anthropogenically introduced (Weldon et al. 2004). Because of its life history (Longcore et al. 1999), *Bd* is typically more prevalent in amphibians that are intimately tied to permanent water bodies (Kriger and Hero 2007). *Bd* appears particularly lethal to amphibians inhabiting relatively mild and stable climates (Longcore et al. 2007) and it is hypothesized that a range of environmental stressors may increase amphibian susceptibility to this disease (see Davidson et al. 2003). Additionally, it is hypothesized that global climate change may be contributing to *Bd* persistence in environments previously unsuitable for this fungus (Pounds et al. 2006). While *Bd* has been identified in amphibian populations globally (see Young et al. 2007), including parts of the northeastern United States (Longcore et al. 2007), data describing its presence in anurans of Cape Cod National Seashore (CACO; Fig. 1), Barnstable County, Massachusetts, USA are non-existent.

CACO is a ca. 17,000 ha national park that is dominated by early-successional landscapes with a multitude of permanent and temporary wetlands that support large populations of several anuran species (Paton et al. 2003), two of which are less common or extirpated (*Anaxyrus fowleri* and *Scaphiopus holbrookii*) elsewhere in New England (see Klemens 1993). CACO is a regional refuge for certain anuran species, but populations are not entirely sheltered from anthropogenic perturbations. Road mortality (U.S. National Park Service, unpubl. data), habitat changes associated with development of adjacent unprotected habitats (Tupper and Cook 2008), recreational use of breeding ponds by park visitors (Tupper et al. 2009), successional changes associated with invasive plants (Smith and Hanley 2005; Tupper and Cook 2008), and extensive predation by large populations of urban-tolerant predators (see MacIvor et al. 1990; O'Connell et al. 2006) are local stressors that contribute to anuran mortality. These stressors, coupled with the implicated effects of climate change and the potential for *Bd* transmission between wetlands by CACO visitors and employees, have the potential to act synergistically (see Alford et al. 2007; Daszak et al. 2005; Di Rosa et al. 2007; Pounds et al. 2006, 2007) to cause declines of anuran populations at CACO.

Here, our goal is to inform anuran management and conservation at CACO by determining if *Bd* is present at CACO and if *Bd* infection rates are significantly different between ecological guilds of anurans. We broadly hypothesized that *Bd* would be present at CACO and that its distributions would be dissimilar among ecological guilds, thus conforming to previously documented distributions (e.g., Longcore et al. 2007; Kriger and Hero 2007).

We opportunistically collected road-killed anurans throughout CACO (for a detailed description of the study area, see Tupper et al. [2007]; Fig. 1) in June, July and August, 2009. All anurans were handled with new latex gloves and placed in individual plastic bags prior to storage at -20°C. To assay for *Bd* presence, animals were thawed and available skin surfaces were thoroughly sampled with sterile dry swabs in March 2010 (no. MW113, Medical Wire and Equipment Company, Durham, North Carolina, USA). Sampling techniques are described by Hyatt et al. (2007). Skin swabs were placed in 1.5 mL microcentrifuge tubes containing 20 µL of proteinase K and 180 µL of digestion buffer. Samples were stored at 56°C and continuously agitated at 550 rpm on a thermomixer (Thermomixer compact, Eppendorf, Hamburg, Germany) for 24 hours. After digestion, we followed protocols from the Qiagen DNeasy kit (Qiagen ®, Valencia, California, USA) to isolate DNA in 30 µL of TE storage buffer (reduced from the protocol volume of 200 µL).

To detect *Bd*, we followed the PCR protocols of Annis et al. (2004) and employed a nested design using modifications similar to those described by Beard and O'Neill (2005) and Goka et al. (2009). Each PCR reaction had a total volume of 25 µL, which included 2 µL of template DNA, 2 µL of primers (Bd1a and Bd2a [Annis et al., 2004] in 10 µM concentrations), 12.5 µL of GreenTaq Master Mix (Promega, Madison, Wisconsin, USA), and 8.5 µL of DEPC water. We modified the thermal cycling protocol used by Annis et al. (2004) to include a +5 sec/cycle time increase to the 1-min elongation step of each cycle. All PCR reactions were visualized on 1–2% TBE or TAE agarose gels. After confirming positive test results (positive control = *Bd* type strain JEL 197) we *ad libitum* sequenced several positive samples to confirm the identity of bands in our gel assay. Resulting

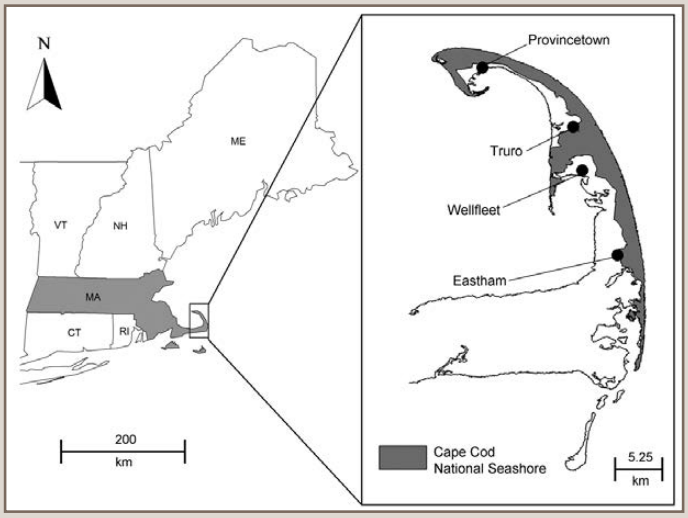

FIG. 1. *Batrachochytrium dendrobatidis* sampling locations at Cape Cod National Seashore, Massachusetts, USA. Localities (towns mentioned in text) near specimen collection sites are indicated on the Outer Cape.

DNA sequences were submitted to GenBank (HQ176488–92). DNA sequence identity was confirmed via BLAST searches in Genbank. Sequence alignments were made using the program Sequencher 4.1 (GeneCodes, Ann Arbor, Michigan, USA). We used a Fisher's exact test (Zar 1999) to assess differences in *Bd* detection rates across two broad ecological guilds (aquatic [*Lithobates* sp.] and terrestrial/arboreal [*Scaphiopus holbrookii, Pseudacris crucifer*, *Anaxyrus fowleri*]). We analyzed data with SPSS version 16 (www.spss.com).

We collected 118 road-killed specimens throughout CACO. Our sampling was distributed across the towns of Eastham, Wellfleet, Truro and Provincetown where we collected 8 (7% of total), 34 (29% of total), 11(9% of total) and 65 (55% of total) samples, respectively. The majority of specimens (N = 114) were collected between 12 July and 1 August 2009. We also used some previously collected material from 5 June 2009 (N = 1) and 2 July 2008 (N = 3). Specimens included representatives of the following species: *Anaxyrus fowleri* (N = 50; 42% of total), *Lithobates catesbeianus* (N = 18; 15% of total), *Lithobates clamitans* (N = 19; 16% of total), *Scaphiopus holbrookii* (N = 17; 14% of total), and *Pseudacris crucifer* (N = 5; 4% of total). We collected several *Lithobates* specimens (*L. catesbeianus* or *L. clamitans*; N = 9; 8% of total) that were not assignable to species because of their disfigurement. Of these specimens, 117 were used in molecular analyses. Twenty one (18%) were *Bd* positive. With the exception of a single *S. holbrookii*, all *Bd*-positive amphibians were *Lithobates* spp. (Table 1), yielding significantly more *Bd*-positive samples from anurans in the aquatic ecological guild (Fisher's exact test; $P < 0.0001$). Of the 21 samples that tested positive for *Bd*, we sequenced 5 and the positive control (SCHO-11, LICA-10, LICL-2, LICL-18, LISP-2, and JEL-197). The resulting DNA sequence for each was ca. 290 base pairs after trimming chromatogram ambiguities. We recovered 3 haplotypes among these fragments each differing by one or two single site polymorphisms.

To our knowledge, this is the first account of *Bd*-infected anurans at Cape Cod, Massachusetts. This study, therefore, provides new distributional data for *Bd* in North America and contributes to the growing pool of evidence indicating that this pathogen is generally widespread. We also document the first reported case of *Bd* detection in *S. holbrookii*. The prevalence of *Bd* infection in our study (18%) was similar to that reported in other parts of New England, USA (13.6%; Longcore et al. 2007). *Bd* detection differed by species, with detections in *L. catesbeianus* and *L. clamitans* and non-detections in *A. fowleri* corresponding to previous surveys in the northeastern United States (Longcore et al. 2007) and other parts of North America (e.g., Ouellet et al. 2005; Rodriguez et al. 2009; Rothermel et al. 2008). Infected individuals of *P. crucifer* have been documented in the southeastern United States (Rothermel et al. 2008) but, as reported here, have not been documented farther north (Ouellet et al. 2005; Longcore et al. 2007). Given our modest sample sizes, however, we cannot conclude that *Bd* is absent from any species in our study area. Our finding that most *Bd* detections were from highly aquatic species is also consistent with other studies (e.g., Longcore et al. 2007; Pearl et al. 2007; Rodriguez et al. 2009), but it is important to note that the presence of *Bd* in *S. holbrookii*, a fossorial species, demonstrates that *Bd* infection is not confined to fully aquatic anurans and, in some cases, spans ecological guilds.

Large-scale morbidity and mortality due to chytridiomycosis have not been observed in anuran species that have tested positive for *Bd* in the northeastern United States. The potential biotic and abiotic factors contributing to this trend are, however, undetermined (but see Longcore et al. 2007 for hypotheses). Also poorly understood are the long-term, sublethal effects of *Bd* in these populations and the possible synergy between *Bd* and other anuran stressors that could alter the virulence of *Bd* in the study region. Our results therefore underscore the importance of long-term monitoring of anuran populations at CACO to detect negative effects of this potentially lethal pathogen. Effective long-term monitoring is especially important for *S. holbrookii* because it is a state-listed threatened species in Massachusetts (http://www.mass.gov/dfwele/dfw/). This species is locally abundant at CACO but uncommon elsewhere in New England (Timm and McGarigal 2010) and difficult to monitor with standardized techniques (R.P. Cook unpublished). Thus, rapid declines associated with

TABLE 1. Amphibian species sampled for *Batrachochytrium dendrobatidis* (*Bd*) at Cape Code National Seashore, Massachusetts, USA.

Species	No. Sampled	No. *Bd* positive (%)
Anaxyrus fowleri	49	0
Scaphiopus holbrookii	17	1 (0.06)
Pseudacris crucifer	5	0
Lithobates catesbeianus	18	7 (0.39)
Lithobates clamitans	19	8 (0.42)
Lithobates spp.	9	5 (0.56)
Total	117	21 (0.18)

chytrid infection at CACO could go undetected and negatively impact New England populations. *Bd* detection in *L. catesbeianus* is also of particular interest because this species is considered a potential *Bd* vector (Daszak et al. 2004). Therefore, we discourage translocation of CACO anurans, particularly *Lithobates* spp., and recommend that equipment and waders be disinfected (Johnson et al. 2003) after visiting wetlands. We also encourage further quantification of *Bd* in *S. holbrookii* populations at CACO.

Unlike in studies that use living or freshly sacrificed frogs, the amount of skin surface available for swabbing in our sample was variable (based on the level of vehicular injury sustained). Inferring *Bd* zoospore load using quantitative PCR (qPCR) could have provided misleading results under these circumstances, so we chose to use the Annis et al. (2004) protocol over qPCR methods. A useful focus for future research at CACO would be *Bd* screening of live anurans from known wetlands in multiple seasons using qPCR, which would allow managers to gain an understanding of the spatial distribution of *Bd* at CACO and zoospore load across seasons.

Acknowledgments.—We are indebted to Joyce Longcore for the donation of several positive controls for this study. Laboratory access at University of Texas at Arlington was generously provided by Eric Smith. We thank Megan Tyrrell of the Cape Cod National Seashore Atlantic Research Center for helping to facilitate this project. Linda Taylor, Scott Buchanan, Megan McLean, Mary Hake, Taylor Harvey, and Kimberly Corwin provided laboratory and field assistance. Molecular aspects of this project were financially supported by a University of Texas at Arlington Phi Sigma honor society grant to JWS.

First Case of Chytridiomycosis in an Adult Specimen of a Native Anuran from Uruguay

In Uruguay, the amphibian chytrid fungus *Batrachochytrium dendrobatidis* (*Bd*) was first detected by Mazzoni et al. (2003). They reported chytridiomycosis in a captive population of *Lithobates catesbeianus* (Anura, Ranidae) which suffered a massive death of metamorphs at a commercial farm. Later, Garner et al. (2006) also confirmed the presence of *Bd* at the same farm and in a new one. Subsequently, Borteiro et al. (2009) found *Bd* by histological analysis in the oral epithelium of native wild species larvae: *Odontophrynus maisuma* (Anura, Cycloramphidae), *Physalaemus henselii* (Anura, Leiuperidae), *Hypsiboas pulchellus* and *Scinax squalirostris* (Anura, Hylidae).

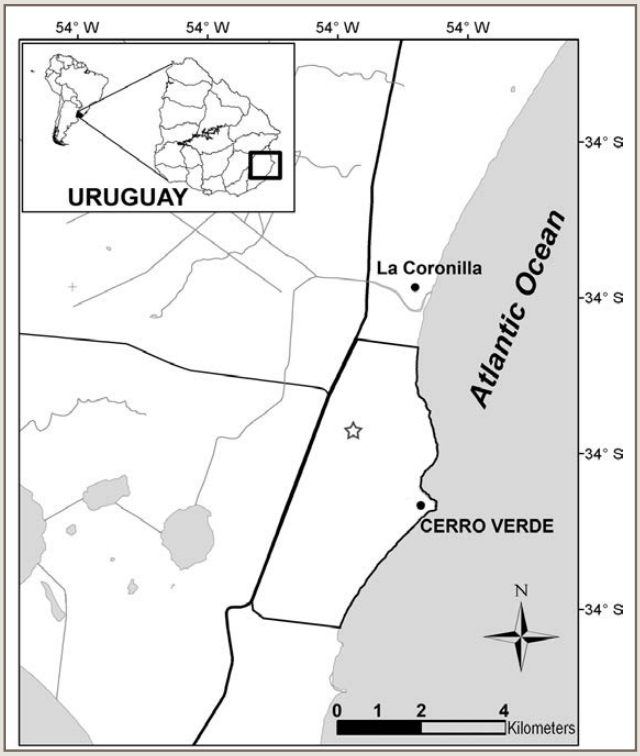

Fig. 1. Location of the Cerro Verde Protected Area, Rocha Department, Uruguay, where *Batrachochytrium dendrobatidis* was detected on *Pleurodema bibroni* (star).

We sampled native, wild amphibians for *Bd* in June 2009 at the Cerro Verde Protected Area, Rocha Department, Uruguay (33.945833°S, 53.508611°W) (Fig. 1). This area is characterized by humid subtropical climate (average temperature 16°C, annual rainfall 950 mm) and an ocean coastline with dunes (20–30 m elevation) and plains (Alonso and Bassagoda 2003). During nighttime sampling, *Pleurodema bibroni* were heard calling at a temporary pond of a coastal meadow. One frog was collected as a voucher specimen of the survey and another individual was collected under suspicion of being infected by *Bd* because it possessed some lesions on the skin (two ulcerations: on right side and dorsum, as described by Berger et al. 2005). Both specimens were taken to the laboratory and the injured frog died a few days later. Both were deposited at Vertebrate Zoology Collection, Facultad de Ciencias, Universidad de la República (ZVC-B 19776, ZVC-B 19775).

To assess the presence of *Bd* in both frogs, skin of the underside of the legs, interdigital membrane of feet, and drink patch was comprehensively swabbed (10 times ea.). Each swab was broken off into an empty Eppendorf tube, and then analyzed

FIG. 2. Skin section of *Pleurodema bibroni* (ZVC-B 19775), collected from Cerro Verde Protected Area, Rocha Department, Uruguay, showing empty *Batrachochytridum dendrobatidis* zoosporangium (EZ) and zoosporangium containing zoospores (Z), one with a discharge tube (DT). Scale bar: 20µm.

for the presence of *Bd* DNA using qPCR (Boyle et al. 2004). *Bd* infection was also analyzed histologically. Abdominal and hind limb ventral skin patches (~5 × 10 mm) and two toe tips were excised from the anurans and routinely processed for histological examination following Berger et al. (1999).

Both analyses (qPCR and histology) were *Bd*-positive only for the apparently healthy specimen. Zoospores and zoosporangia at different stages were found at multiple sections of toe tips and hind limb of the infected individual, and some degree of hyperkeratosis at the sections from hind limbs of the specimen was found (Fig. 2).

This is the first record of *Bd* in an adult native wild-caught amphibian in Uruguay, and the first report of *Bd* infection for *Pleurodema bibroni*. This frog is considered Near Threatened by the IUCN Red List (IUCN 2006) and is Threatened at a country level for Uruguay (Maneyro and Langone 2001; Canavero et al. 2010). The pathogen was detected 100 km northeast of the nearest record in Uruguay (Borteiro et al. 2009) inside a Protected Area, which is both alarming and suggests that measures for control and prevention of human-mediated *Bd* dispersal warrant consideration. This is particularly important because populations of other native species in the area, such as *Melanophryniscus montevidensis* (Núñez et al. 2004), may be at risk (IUCN RED LIST: Vulnerable; IUCN 2006).

Acknowledgments.—We thank M. Bessonart and F. Féola from the Facultad de Ciencias for their support for histological analysis at the Estación Experimental de Investigaciones Marinas y Acuicultura, K. Gore and M. Perdue for molecular analysis, F. Gallego for graphical assistance, and I. Berro and A. García for invaluable help during field surveys.

Resumen.—En Uruguay la infección causada por *Batrachochytrium dendrobatidis* (*Bd*) había sido detectada en *Lithobates catesbeianus* de criaderos comerciales y en larvas silvestres de especies autóctonas, pero no había sido confirmada aún en ejemplares adultos de ninguna especie nativa. En junio de 2009 se colectaron dos machos adultos silvestres de *Pleurodema bibroni* en el Cerro Verde (33.935°S, 53.5070556°W, Rocha, Uruguay), se les tomaron muestras para análisis de ADN (qPCR) para detectar *Bd*. Uno de ellos resultó positivo y el análisis histológico de la piel del ejemplar también confirmó la infección. Por tanto se diagnostica por primera vez la infección por *Bd* en adultos silvestres de esta especie en Uruguay, que además está considerada como *Amenazada* a nivel nacional y *Near Threatened* para la IUCN.

First Survey of the Chytrid Fungus, *Batrachochytrium dendrobatidis*, in Amphibian Populations of Gabon, Africa

First associated with amphibian declines in 1998 from amphibian populations in Australia and Panama, the amphibian chytrid fungus *Batrachochytrium dendrobatidis (Bd)* has since been detected in amphibian populations in all continents except Antarctica, and additional mass-mortalities thought to be caused by *Bd* are continually being observed (Berger et. al. 1998, 2004; Bosch et. al 2001; Lips 1998; Lips et al. 2003, 2006). Weldon et al. (2004) found *Bd* on amphibian specimens collected from South Africa in the 1930s, the earliest date of a *Bd* record, and suggested that *Bd* originated in the continent of Africa. Analyses of museum specimens by Soto-Azat (2010) corroborated this hypothesis. Yet to date, *Bd* surveillance in Africa has been limited. The few studies that have been carried out have confirmed the presence of *Bd* in Africa, including: 1) in Uganda, six amphibian species tested positive for *Bd* (Goldberg et. al. 2007); 2) in Kenya, *Bd* was found in all of amphibian populations sampled in several habitat types (Kielgast et. al. 2010); 3) in eastern Democratic Republic of Congo, *Bd* was detected in two species (Greenbaum et al. 2008); and 4) evidence of *Bd* was found in amphibians in Okomu National Park, Nigeria (Imasuen 2009; Reeder et al., *in press*). In light of the confirmed existence of *Bd* in Africa, regions where data are lacking warrant surveys for this pathogen.

Gabon is located in the equatorial region of the Atlantic coast of Central Africa (Fig. 1), contains an exceptionally high diversity of amphibian species (IUCN 2004), and is in close proximity to the West African forests that have been denoted a global biodiversity "hotspot" (Myers et al. 2000). Yet to date, no *Bd* sampling has been conducted in Gabon. In fact, there are remarkably few published reports of *Bd* surveys from the tropical forests of Central and West Africa (www.Bd-maps.net): two studies in Cameroon (Blackburn et al. 2010; Dougherty-Bone et al. 2008) and one study in the Democratic Republic of Congo (DRC) (Greenbaum et al. 2008). Our aim was to determine the incidence of *Bd* in amphibian populations in Gabon. The results of our study contribute to the expanding body of literature on the global distribution of *Bd* and aid the determination of priority areas for amphibian conservation in equatorial Africa.

Surveys were conducted from July through September 2008, months coinciding with the dry season, in three regions of Gabon: Lastoursville (-0.816815°S, 12.708026°E), located on the banks of the Ogooué River in eastern Gabon; Lebamba (-2.210605°S, 11.476516°E); and the Station d'Etudes des Gorilles et Chimpanzés (SEGC), located within the 4970 km^2 Lopé National Park (0.166667°S, -0.266667°E) (Fig. 1). The Lastoursville and Lebamba region contain extensive Guineo-Congolian tropical forest (Plana 2004), though much of our sampling occurred in villages and agricultural areas that have been cleared of forest. SEGC lies in a lowland area featuring savannah patches that are interspersed with gallery forests and small forest fragments, referred to locally as "bosquets." Flanking the savannahs is a block of continuous forest in various stages of succession but typically Marantaceae and mature forest (Dowsett and Dowsett-Lemai 1991; White and Abernethy 1997; Christy and Wilmé 2003). Surveys were performed in conjunction with a survey of caves in this country, and thus, surveys focused on cave-dwelling species. With the exception of the Grotte de Lastoursville, the caves that were surveyed were located within the vicinity of Lebamba, including: the Grotte de Lebamba, the Dilime de Mutsobulu, the Grotte de Bangouéguelé, the Grotte de Munganga, the Grotte de Diengu, and the Grotte de Mbenaltembe (for detailed account of each cave, see Frost and Testa 2009). In general, the caves were moist and had flowing water. During the wet season, many of these caves flood entirely. Local villagers and bat hunters occasionally frequent the caves, but none were developed for tourism. Caves were typically surrounded by forestland, except the Grotte de Diengu, which was located in an agricultural field.

Sampling for amphibians was performed in an opportunistic manner along roads and trails, around cave entrances, and inside cave chambers. A tissue sample was collected from each captured individual by rubbing a sterile cotton swab over the ventral side of the body and thighs (20 strokes) and the webbing of the hind feet (10 strokes). Swabs were placed into microcentrifuge tubes, stored in freezers at SEGC and later exported to the Museo Nacional de Ciencias Naturales in Madrid (CSIC), Spain. Here, swabs were analyzed for the presence of *Bd* following Boyle et al. (2004). Positive controls were not used, but samples that tested positive for *Bd* from other surveys were included in the same analysis. That samples in the same plate tested positive confirms the functionality of the analysis. Geographic coordinates were recorded for each capture location using a Global Positioning System (GPS). When animals were captured inside a cave, coordinate locations of the cave entrance were used. Photographs of each morphotype were taken for subsequent species identification.

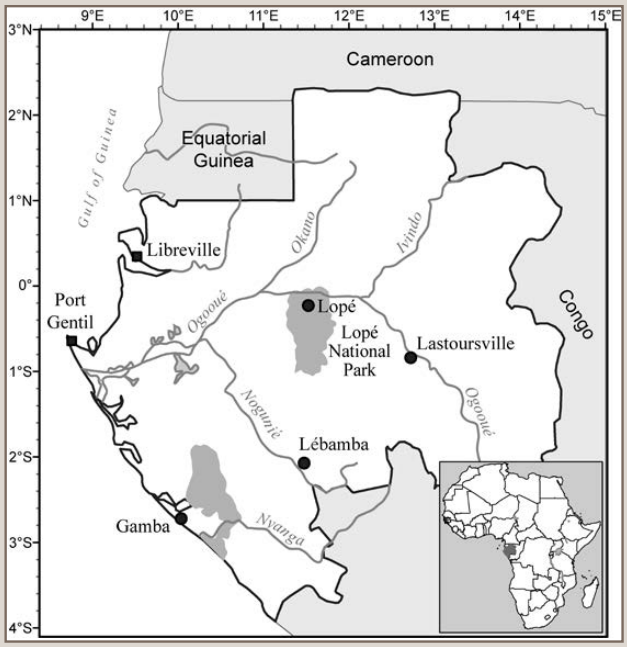

FIG. 1. Locations of Lastoursville, Lebamba, and Lopé National Park, Gabon, where amphibians were sampled for *Batrachochytrium dendrobatidis*.

Fifty adult frogs were captured throughout the study period, 29 of which were cave-dwelling species. Five individuals were captured in the area of Lastoursville. Of these five individuals, two *Amietophrynus* cf. *camerunensis* and one *Arthroleptis poecilonotus* were encountered along dirt roads and walking paths surrounding the town. One *Ptychadena aequiplicata* was found approximately 150 m inside the Grotte de Lastoursville.

In the Lebamba region, 35 amphibians were captured. Seven *Petropedetes* cf. *vulpiae* were found at the entrance of the Grotte de Lebamba. Three *Phrynobatrachus* cf. *auritus* were captured along a logging road that led to the cave entrance. Four amphibians were found in open grassy areas: two *Amietophrynus maculates* and two *Arthroleptis poecilonotus*. Six *Petropedetes* cf. *vulpiae* were found at the entrance of the Grotte de Bangouéguelé. One *Petropedetes* cf. *vulpiae* was found at the Dilme de Mutsobulu. Six *Petropedetes* cf. *vulpiae* were captured in the Grotte de Munganga/Iduku. When sampling in the Grotte de Diengu, seven *Phrynobatrachus* cf. *auritus* were captured. One *Petropedetes* cf. *vulpiae* was captured at the Grotte de Mbenaltembe under a rock pile at the entrance of the cave. In this region, all cave-dwelling frogs were found within the first 15 m of the cave entrance under rock piles or inside nooks in the cave walls.

In Lopé National Park, 10 *Cardioglossa leucomystax* were captured. Except for one individual, which was captured along a dirt road leading to the SEGC biological station, these frogs were found along sandy streambanks in maratanacae forest.

Bd was not detected in any of the 50 samples collected from these animals. Comparing these results to surveys done in other Central African countries, our findings mirror those from surveys in the neighboring country of Cameroon, where *Bd* was absent as well (Blackburn et al. 2010; Doherty-Bone et al. 2008), but differ from the surveys done in eastern DRC, where *Bd* was detected (Imausen 2009; Reeder et al., *in press*). Despite our findings, continued surveillance of *Bd* in Gabon and the Central African region is warranted. Skerratt et al. (2008) reported that 59 animals should be sampled to detect *Bd* when prevalence is low, hence we cannot rule out the possibility that *Bd* occurs on our sampled species at our sampled sites in Gabon at a low prevalence rate. Furthermore, in an extinction-risk assessment for *Bd*, Gabon occurred in an area of both high susceptibility to *Bd* and high amphibian richness (see Figure 2B in Rödder et al. 2009). Thus, our report should not discourage future surveys of *Bd* prevalence in Gabon but rather act as a reference by which to plan and execute more focused and expansive *Bd* monitoring activities in this region.

Acknowledgments.—We thank the Centre National de Recherche en Science et Technologie for research authorization in Gabon and the Agence Nationale des Parcs Nationaux for park authorization in Lopé. We are grateful to the Centre International de Recherches Médicales de Franceville (CIRMF) for hosting the research at SEGC. We would like to thank N. Pistole, M. Oliphant, M. Laumanns, and T. Frost for assistance with amphibian surveys in Gabon; D. Blackburn, M. Rödel, O.S.G. Pauwels, J. Harvey, and T. Fretey for assistance with species identification; El Museo Nacional de Ciencias Naturales (CSIC) for providing laboratory resources for this study; and V. Vredenburg and T. Garner for assistance with manuscript revisions.

Batrachochytrium dendrobatidis Not Detected on Amphibians from Two Lowland Sites in Gabon, Africa

Batrachochytrium dendrobatidis (*Bd*) is behaving as an invasive pathogen in many parts of the new world where it has been associated with massive amphibian declines in native populations (Berger et al. 1998; Lips et al. 2006; Lips et al. 2008; Soto-Azat et al. 2010). *Bd* has also been found on various Pipidae species in South Africa, Uganda, Malawi and Cameroon from as early as the 1930s, suggesting a widespread historical prevalence on the continent (Soto-Azat et al. 2010; Weldon et al. 2004). Despite these observations, many areas in Africa have not been systematically surveyed for *Bd*. Contemporary *Bd* distribution data are sorely lacking in West and Central Africa, including for Gabon (http://www.bd-maps.net). Yet, such data may prove critical in assessing the risk of *Bd* infection to amphibians on the continent, and identifying its ultimate origin.

In November to December 2009, we surveyed amphibians for *Bd* at two lowland areas in Gabon (Fig. 1). The first site was located in the SW region of the country around the town of Gamba (2.78676°S, 0.04551°E; elevation 0–100 m). The area is a coastal plain covered by a mosaic of rainforest patches interspersed with open, seasonally inundated grasslands (Alonso et al. 2006). The second site was at the Libreville campus and surrounding areas of L'Ecole Nationale des Eaux et Forêts training center in the NW region of the country (0.6030167°N, 9.3372667°E; elevation 0–100 m). It is covered by primary and secondary rainforest with many streams, but most amphibians at this site were found in temporary wetlands formed in open grassy areas adjacent to the forest. At each site we opportunistically searched for amphibians in forests, streams, wetlands and ditches. Amphibians were captured with a gloved hand and were brought indoors for processing where they were swabbed with a sterile cotton swab (10 strokes on the belly and thigh,

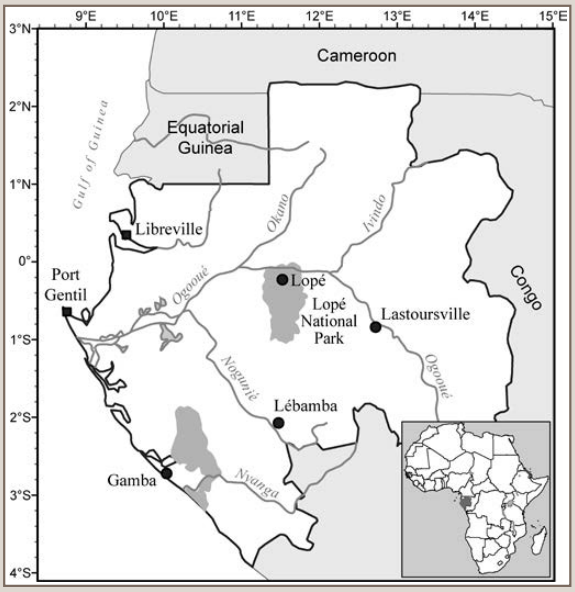

FIG. 1. Locations of Libreville and Gamba, Gabon, where amphibians were sampled for *Batrachochytrium dendrobatidis*.

TABLE 1. Amphibian species tested for *Batrachochytrium dendrobatidis* (*Bd*) at two sites (Gamba and Libreville) in Gabon.

Species	Gamba	Libreville	*Bd* positive
Afrixalus dorsalis	3	7	0
Amietophrynus regularis	4	0	0
Chiromantis rufescens	0	5	0
Hoplobatrachus occipitalis	6	0	0
Hyperolius spp.	10	32	0
Hyperolius tuberculatus	2	9	0
Hyperolius cf. *cinnamomeoventris*	3	1	0
Hyperolius nasutus	25	2	0
Hyperolius phantasticus	15	0	0
Hyperolius platyceps	1	0	0
Leptopelis aubryi	1	1	0
Leptopelis sp. (juvenile)	2	0	0
Phlyctimantis leonardi	6	2	0
Phrynobatrachus auritus	1	0	0
Ptychadena sp.	1	5	0
Xenopus epitropicalis	6	2	0
Totals	86	66	0

and five strokes on each foot). Swabs were stored in tissue buffer prior to DNA extraction. Specimens were identified to the extent possible in the field using a small reference collection of specimens housed on site at Gamba. We retained 129 specimens for the Smithsonian's National Museum of Natural History (USNM 578099 – 578232) Washington, DC, USA. We swabbed and released an additional 24 *Hyperolius* spp. at Libreville.

Each swab was incubated in an oscillating thermal incubator at 56°C and 350 rpm in 400 µl of buffer ATL (Qiagen) and proteinase K (Qiagen) for 24 h. After incubation, DNA was extracted from the lysate solutions using a Qiagen Biosprint 96 DNA Blood Kit according to the manufacturer's instructions for "extraction from buccal swabs." Extracted DNA was eluted in 200 µl of AE buffer (Qiagen) and stored at 4°C prior to further analysis. To ensure successful DNA extraction, a fragment of 16s mRNA was amplified for each sample, including negative controls (N = 10), and visualized on 2% agarose gels. Testing for the presence of *Bd* was performed using a Qiagen QuantiTect SYBR Green PCR Kit using the primers ITS1-3 Chytr and 5.8s Chytr, developed by Boyle et al. (2004). To identify potential false positive and false negative results, two positive and two negative controls were included in every PCR reaction; false positive/negative results were not obtained.

A total of 86 frogs from Gamba and 66 frogs from Libreville were sampled, represented by five families (Table 1); all were *Bd*- negative. We used a binomial distribution to calculate the maximum potential prevalence rate using a 95% confidence limit with our sample of 0 infected swabs (successes) from 152 frogs (trials). Assuming 100% *Bd* detectability on all animals swabbed, we can be 95% confident that—if *Bd* is present in wild frogs at these two sites—prevalence rates are lower than 2%. While we cannot rule out non-detection as a reason for its supposed absence, we can say that if *Bd* is present, its prevalence in this region is extremely low and thus unlikely to be having any significant ecological impact on the sampled populations. These data as well as those of Daversa et al. (2011, this issue) therefore lend support to climate models which predict *Bd* has a low probability of affecting amphibian populations in lowland areas (Rödder et al. 2009).

Acknowledgments.—We are grateful to field and financial support from Shell Gabon, and the Smithsonian Conservation Biology Institute's Center for Conservation Education and Sustainability. Ecole Nationale des Eaux et Forêts provided logistical support. We also thank the Government of Gabon for giving us permission to conduct the study and to export the specimens, and M. Butler, T. Leuteritz, and O. Pauwels for providing valuable logistical advice and assistance. This is publication #134 of the Gabon Biodiversity Program.

First Record of the Chytrid Fungus *Batrachochytrium dendrobatidis* in North Africa

An important driver of amphibian declines is chytridiomycosis, a disease caused by the pathogen *Batrachochytrium dendrobatidis* (*Bd*; Berger et al. 1998; Bosch et al. 2001; Collins and Storfer 2003; Daszak et al. 1999, 2003; La Marca et al. 2005; Ron and Merino-Viteri 2000; Ron et al. 2003; Wake and Vredenburg 2008; Walker et al. 2010). *Bd* is now known to be an emerging pathogen that is rapidly expanding its global range (Fisher et al. 2009) and now has attained a global distribution on all continents that contain amphibians (www.bd-maps.net). Research by Weldon et al. (2004) on the potential origin of *Bd* suggests that the panzootic originated in South Africa and has perhaps been dispersed by international trade in amphibians, becoming established around the world (Rödder et al. 2009). To date, the rapid and widespread distribution of *Bd* infection across hundreds of amphibian species is alarming.

In Spain, outbreaks of chytridiomycosis and mass mortalities has been reported in many species and in different regions of the country (Bosch et al. 2001; Bosch and Martínez-Solano 2006; Walker et al. 2008, 2010). In the south of Spain, *Bd* is widely distributed (www.bd-maps.net); Bosch et al., unpubl. data), suggesting that its occurrence in northern Morocco is plausible. The two regions are spatially proximate with similar Mediterranean ecologies, however, they are separated by the Straits of Gibraltar. In addition, ecological niche modelling has shown that the environmental envelope in northern Morocco is suitable for the establishment of *Bd* where susceptible amphibians occur (Rödder et al. 2009; Ron 2005). The legal and illegal increase in the transport of animals for pet trade (Fisher and Garner 2007), and the possibility that the fungus could be vectored into Morocco on the feathers of water birds, are potential modes of transmission between Spain and Morocco. However, no systematic surveillance for *Bd* has been undertaken across this region, where several endemic species occur with a high ecological value. The aim of the present study is to conduct the first survey for *Bd* in northern Morocco to determine the presence, prevalence, and intensity of infection in the amphibian populations that occur within the region. These data will allow us to understand the distributional patterns of *Bd*, providing essential data for the effective management and control of this emergent pathogen.

Surveys for *Bd* were conducted between October 2005 and April 2009. During this period, we prospected the north of Morocco which is primarily a mountainous area (central-western Rif and north part of middle Atlas). Samples from the plain of Gharb and the Mammora regions were provided by P. de Pous (University of Applied Science van Hall-Larenstein, the Netherlands). The Rif region forms a mountainous barrier that is relatively low in elevation (less than 2500 m) with approximately half of the surface occurring above 500 m. It is an extension of the Baetic Cordillera, which includes the Sierra Nevada in the south of Spain. The area is a sub-wet zone with an average annual rainfall between 800 and 1400 mm (Bab Taza: 1361 mm/year), and probably reaches 2000 mm on the highest summits, and wetlands are common. In comparison, the coastal fringe is dry, where rainfall does not reach 500 mm (Oued Laou, 473 mm). Across the coast, the summer is moderate in temperature (Oued Laou, mean maximum temperature of the hottest month: 28.6°C), however weather stations located inland record

much higher temperatures (Chefchaouen, mean maximum temperature of the hottest month: 33.8°C). In general, winter is the season when thermal contrasts are most variable, according to the altitude and of the distance of the sea. The coastal fringe has a mild winter (Oued Laou, mean minimum temperature of the coldest month: 7.2°C), with high-altitude areas recording harsher winters (Bab Taza, mean minimum temperature of the coldest month: 2.3°C). Separated from the Rif region by the corridor of Taza, the middle Atlas is the westernmost of three Atlas Mountains chains existing in Morocco. Its geomorphologic structure is primarily constituted by limestone (with an altitude more than 3000 m) and volcanic plates. The western façade, with the oceanic influence, is the most humid part (approximately 1000 mm/year). More continental than Rif, the middle Atlas experiences harsh winters, with snow occurring above 2000–2500 m elevation. The Riffian and the middle Atlas forests are rich and are characterized by a gradient of elevation on which are overlaid continental, oceanic, and Mediterranean influences. The plain of Gharb and the forest of Mammora are located at the northwest of Morocco. The first is a basin characterized by a Mediterranean-type climate with an oceanic influence. The east-west rainfall gradient varies between 450 and 530 mm, with 80% of the total rainfall occurring during the winter. In its south, the forest of Mammora is located in the semi arid bioclimatic zone. It is in extreme limit of the natural distribution surface of the Mediterranean cork oak. This marginal geographical location makes this ecosystem particularly fragile. All of these prospected ecosystems are indispensable for animal species, particularly amphibians, and are experiencing increasing deterioration under the effect of sustained anthropogenic pressures.

Amphibian specimens were collected opportunistically from 28 sites on the Rif region, 11 sites on the middle Atlas and 12 sites on the Gharb plain and Mammora forest (Table 1; Fig. 1). During nocturnal and occasional diurnal surveys, we extensively searched all water bodies that exist in the survey areas for amphibian larvae. We also searched for adults in the areas surrounding ponds. Immediately after capture, we took samples including toe clippings from adults and swabs from the mouthparts from tadpoles (MW100-100; Medical Wire & Equipment Co, Corsham, UK). Toe clippings were preserved in 70% ethanol for laboratory analysis. After sampling, animals were returned to their place of capture. The intensity of infection was subsequently assessed in the laboratory using the quantitative PCR (qPCR) protocol described by Boyle et al. (2004).

We sampled 203 amphibian specimens representing six families and nine species captured from 51 sites (Table 1). Of these, 96 specimens were collected in the Rif mountains, 42 in the Middle Atlas and 64 in the Gharb plain. *Bd* was confirmed in just four amphibians collected from three sites (Table 1, Fig. 1); *Bd* was found in *Discoglossus scovazzi* in the Tetouan region and in *Hyla meridionalis* and *Pelobates varaldii* in the Larache-Lakser Lakbir region (total prevalence 6%). Rare detection of the fungus occurred, with 1/1 in Agnane (intensity of infection: 29.9 genome equivalents, GE), 2/5 in Larach-Lakser lakbir (intensity of infection: 60.3 and 395.9 GE) and 1/10 in Larach (intensity of infection: 0.4 GE), demonstrating a low prevalence of infection for the fungus across these three sites.

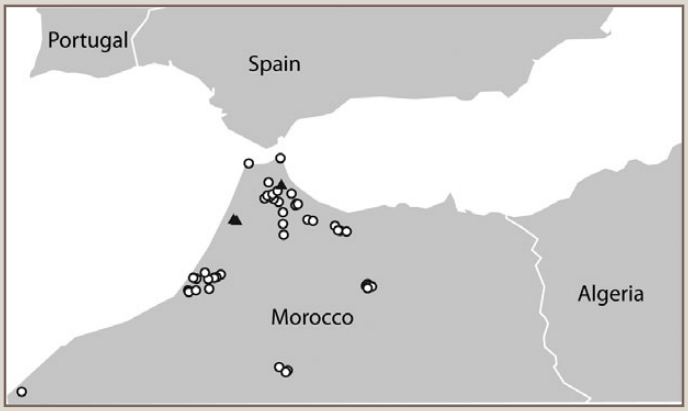

FIG. 1. Map of northern Morocco showing *Batrachochytrium dendrobatidis* (*Bd*) sampling locations that were *Bd*-positive (closed triangle) and *Bd*-negative (open circles).

In Morocco, many populations of amphibian species are endangered and local declines of several species have been principally attributed to two threats: habitat destruction and pollution. However, no work has been conducted previously to assess the presence of *Bd* on the amphibians living in the country. In our study, we confirm the presence of *Bd* in Morocco and consequently in North Africa. This region of the world is not free of *Bd*, a finding that is in accordance with the models of Ron (2005) and Rödder et al. (2009), which predicted suitable habitats for *Bd* in north Morocco. The niche distribution models of Ron (2005) assigned a maximum overlap index of 1 to this region, which means that 10 of 10 models predicted the survival of *Bd*, should susceptible amphibian species exist.

The presence of *Bd* in Morocco and particularly in the north part of the country can be explained by several mechanisms. The presence of chytrid fungus in peninsular Iberia, especially in the south of Spain where it is broadly distributed, may have been vectored to the northern part of Morocco by anthropogenic or natural processes. For example, during a survey in southern Spain performed in 2004, 31% of 86 collected samples and 29% of 17 sampled localities were *Bd*-positive (Bosch et al., unpubl. data). The border between the two countries experiences the extensive transport of industrial and agricultural products and animals across the straits of Gibraltar. Moreover, the presence of two Spanish enclaves at the north of Africa without customs and borders with the remainder of continental Spain makes the possible contamination of North Africa by *Bd* more real. However, natural vectors may also transport *Bd*. The fungus is able to survive and remain infectious for 3–6 weeks in the environment in the absence of an amphibian host (Johnson and Speare 2003), may attach to plant debris and microorganisms within sterile environments, and can perhaps persist in soil as do some other members of the phylum Chytridiomycota (Johnson and Speare 2005). These life-history characteristics of chytrid fungi allow prediction (and possible prevention) of its potential accidental transport via the movement of soil such

TABLE 1. Localities in northern Morocco where amphibians were sampled for *Batrachochytrium dendrobatidis* (*Bd*). Species: Am- *Alytes maurus*, Ds- *Discoglossus scovazzi*, Bm- *Bufo mauritanicus*, Sa- *Salamandra algira*, Hm- *Hyla meridionalis*, Ps- *Pelophylax saharicus*, Bb- *Bufo bufo*, Pb- *Pseudepidalea boulengeri* (= North African populations of *Bufo viridis* s.l.), Pv- *Pelobates varaldii*, Pw- *Pleurodeles waltl*. Life history stage (LHS): A- adult, L- larvae, J- juvenile, M- metamorph. N = sample size, IA = number of infected animals, range of *Bd* infection loads (*Bd* IL) in genomic equivalents detected using quantitative PCR.

as in extraction industries, in contaminated soil on vehicles or footwear of hikers, or in plant nursery products (Johnson et al. 2003; Johnson and Speare 2005; Laurance et al. 1997). However, the dissemination by water birds through the migration routes between Europe and Africa via the Gibraltar strait may be responsible for facilitating the spread of the pathogen across this region, and this process is largely uncontrollable, rendering effective biosecurity of northern Africa unlikely.

Our surveys were by no means exhaustive and further research on both the distribution and effect of the pathogen across this region is needed. Our data show: 1) three *Bd*-positive sites (1/1 in Agnane, 2/5 in Larach-Laks lakbir, and 1/10 in Larach); and 2) a clustering of *Bd* in the western part of northern Morocco, just in the south of Tangitana peninsula (Fig. 1). This distribution supports the hypothesis of a dissemination of *Bd* from the Iberian Peninsula to northern Morocco. However, confirmation of this hypothesis awaits molecular typing of isolates of *Bd* that have been recovered from these infected Moroccan populations.

Our results suggest a systematic survey of the area is warranted in order to determine the exact situation in the region. Furthermore, biosecurity and population management measures warrant consideration to prevent further amphibian species loss owing to this emergent pathogen.

Acknowledgments.—We thank P. de Pous and M. Radi for their field assistance. This study was financed by the cooperative Convention between CNRST (Morocco) and CSIC (Spain) N° 644-06 and the Spanish Agency for International Cooperation, AECI (project PCI A/9803/07). The capture of animals and transport of tissues samples from Morocco to Spain was conducted under the Moroccan Water and Forest Service: Authorisation N° 2988/ E HCEFLCD/DLCCDPN/CFF.
